[DOI: 10.1063/1.2206592]

Silicon is an important semiconductor for manufacturing of microelectronic chips used in computers and other electronic devices. During the manufacturing process, liquid silicon is being solidified to make high-grade solid semiconductors. Thus, improved data of the solid-liquid interfacial properties of silicon will be useful towards optimizing the experiment condition for making better quality electronics. Yet it is difficult to perform experiments of liquid silicon due to its high melting point. Thus far, most experimental measurements of the solid-liquid interfacial tension are based on the measurement of rate of homogeneous crystal nucleation at a given undercooling. The first measurement of solid-liquid interfacial tension of silicon was performed by Stöffler et al. Following pulsed-laser melting thin films of silicon, a deep undercooling of 505 K was achieved. The measured rate of nucleation is about $10^{29}$ events/s m$^3$, which yields a solid-liquid interfacial tension $\gamma_{sl} = 0.34 \pm 0.02$ J/m$^2$. The estimation of surface tension is based on the assumptions that the critical nucleus is spherical and the nucleation is homogeneous.

Besides thin films of silicon, deep undercooling has also been achieved in bulk liquid silicon using containerless processing techniques, such as electrostatic levitation,\textsuperscript{2} flux processing,\textsuperscript{3} and electromagnetic levitation.\textsuperscript{4–6} Shao and Spaepen\textsuperscript{7} processed pure Si drops about 1 mm in diameter processing,\textsuperscript{3} and electromagnetic levitation.\textsuperscript{4–6} Shao and Spaepen\textsuperscript{7} processed pure Si drops about 1 mm in diameter undercooling up to 330 K was produced.\textsuperscript{6} The estimated solid-liquid interfacial tension $\gamma_{sl}$

\begin{equation}
\beta = (A_0 - b \log_{10} Q) \theta_c (\theta_c - 1)^2, \tag{1}
\end{equation}

where $A_0 = 59.4$, $b = 2.33$, and $Q$ is normalized by $Q_0 = 1$ K/s. The dimensionless temperature $\theta_c = T^+ / T_m$ or $T^- / T_m$, where $T_m$ is the melting temperature. In the case of silicon, $T^-$ is much more difficult to determine because of the transition of silicon from liquid to amorphous under the fast cooling rate in molecular dynamics (MD) simulations.\textsuperscript{14–17} Hence, we calculate $\beta$ by using only the superheating temperature and the melting point of respective silicon model. Once $\beta$ is obtained, solid-liquid interfacial tension ($\gamma_{sl}$) can be calculated by

\begin{equation}
\gamma_{sl} = \left( \frac{3}{16 \pi \beta \sigma T_m \Delta H_m^2} \right)^{1/3}, \tag{2}
\end{equation}

where $\Delta H_m$ is the enthalpy change per unit volume between the solid and liquid phases at the melting point.

We deployed both Stillinger-Weber (SW) and Tersoff-89 (Ref. 19) models to compute $\gamma_{sl}$ of silicon. The reduced units of energy ($\varepsilon$) and length ($\sigma$) for SW model are $\varepsilon = 3.4739 \times 10^{-19}$ J and $\sigma = 0.2951$ nm, while for the Tersoff-89 model they are $\varepsilon = 1.6022 \times 10^{-19}$ J and $\sigma = 0.1$ nm. Each MD time step corresponds to 0.5 fs. The simulations started with crystalline silicon structures of $5 \times 5 \times 5$ cell units, which contain 1000 atoms, and a temperature of 1000 K for SW model and 2000 K for Tersoff-89. Two heating rates were applied to the structure. The heating rate of $1 \times 10^{11}$ K/s increase the temperature of the system by 12.5 K every 250 000 steps, while that of $5 \times 10^{11}$ K/s increases the temperature by 12.5 K every 50 000 steps. The first 5000 steps after the heating was for equilibration, and thermodynamic data were measured for the remaining steps until the next temperature increase. The cooling process was performed when the temperature of the system reached 3000 K for SW and 4000 K for Tersoff-89 model. The structure was then being cooled down to 500 K (1500 K for Tersoff-89) using the same rate as the heating. Potential energy and volume were recorded during the process in order to evaluate free energy using Monte Carlo simulations.\textsuperscript{9}

\textsuperscript{12} using a superheating/undercooling method in molecular simulation,\textsuperscript{11} Luo et al. simulated solid-liquid transitions of a Lennard-Jones system as well as water/ice system and reported their solid-liquid interfacial tensions. In this short note, we apply the simulation method of Luo et al.\textsuperscript{11} to calculate solid-liquid interfacial tension of silicon.
to observe the superheating/undercooling temperature. The systems were run in isobaric-isothermal (NPT) ensemble by using the Nose-Andersen method. Pressure of the systems was set at zero for all simulations.

Silicon crystal undergoes superheating during the heating process and the structure melts at a temperature higher than the melting points (Table I). The melting points of the structure were determined by the coexisting solid-liquid phase method. The melting point of Tersoff-89 model is 2567 K, which is higher than both experimental value and the SW model. A potential energy of the system versus temperature curve shows that the system undergoes a phase transition at the superheating temperature ($T^*$) (Fig. 1). The ratio of superheating temperature to melting temperature is quite high due to the strong covalent bond in silicon crystal. During the cooling process, the potential energy and volume of silicon do not show a sudden change as observed in superheating, in part due to the use of rapid cooling rates. The volume of the system with increasing temperature is shown in Fig. 2. Similar to potential energy curves, a sudden drop of volume is observed when the crystalline structure of silicon breaks down. However, in the cooling process, the volume increases gradually with decreasing temperature during the transition. A larger fluctuation is observed with the Tersoff model [Fig. 2(b)], which is likely due to a much higher starting temperature than the SW model.

Once we calculated the nucleation barrier parameter ($\beta$), we can determine the solid-liquid interfacial tension ($\gamma_{sl}$) by Eq. (2). Since the simulation was carried out at zero pressure, the enthalpy change at melting point is equal to the change of internal energy of the system. We calculate the difference of

TABLE I. Physical properties of silicon in the superheating process. Heating rate ($Q$), superheating melting point ($T^*$), melting point ($T_m$), ratio of superheating melting point to melting point ($\theta_s$), nucleation barrier parameter ($\beta$), average volume per atom ($V$), enthalpy change per unit volume between solid and liquid states at melting point ($\Delta H_m$), and solid-liquid interfacial tension ($\gamma_{sl}$) are displayed. The first two rows are results of the Stillinger-Weber model and the last two rows are those of the Tersoff-89 model.
enthalpy between the solid and liquid states at the melting point. We then divided the values with the mean molar volume of the solid and liquid to obtain the enthalpy change per unit volume at melting point. The average $\gamma_{sl} \sim 0.413 \text{ J/m}^2$ (Table I), which is in good agreement with the measured result, ranging from 0.34 to 0.4 J/m$^2$. Moreover, the two silicon models give very close values of $\gamma_{sl}$, even though the two models give dramatically different melting points. This suggests that the value of $\gamma_{sl}$ is less sensitive to the model. Using a different heating rate also does not affect the final result of $\gamma_{sl}$, as shown in Table I. Finally, we note that the $\gamma_{sl}$ of SW silicon is about half the value of the liquid-vapor surface tension ($\sim 0.8 \text{ J/m}^2$).\footnote{In summary, we have deployed the superheating method of Luo et al. to compute the solid-liquid interfacial tension of silicon. Since there is no other computer simulation report on $\gamma_{sl}$ of silicon, we hope that this piece of data can provide a useful benchmark on the interfacial properties of the two models of silicon. It is known that surface tension can be lowered appreciably when impurities (e.g., oxygen) exist in the structure. Research in this direction is under way.

The authors are grateful to valuable discussion with Dr. J. Morris. This work is supported by grants from the DOE (DE-FG02-04ER46164) and the Nebraska Research Initiative, and by John Simon Guggenheim Foundation and the Research Computing Facility at University of Nebraska-Lincoln.
