(Received 26 November 2001; accepted for publication 25 February 2002)

The experimentally measured coercive electric fields for domain reversal in ferroelectrics are typically many orders of magnitude lower than the estimates from phenomenological free-energy theory. This letter specifically investigates the influence of polarization gradients at pre-existing 180° domain walls in ferroelectrics on coercive fields for domain wall motion. It is shown that the ratio of theoretical coercive field without and with a preexisting domain wall is directly proportional to the ratio $x_o/a$, where $a$ is the lattice parameter and $2x_o$ is the polarization wall width. This factor is 7.5–45 for a 20–120 nm wall width, the latter width determined here as the experimental upper limit for polarization wall width in lithium tantalate. © 2002 American Institute of Physics. [DOI: 10.1063/1.1470247]

Why are the experimentally measured coercive fields for domain reversal in ferroelectrics many orders of magnitude smaller than theoretical estimates? The question mirrors a domain reversal in ferroelectrics many orders of magnitude lower than experimentally observed deformation shear stresses (e.g. $\sim 10^{10}$ N/m$^2$ in metals) many orders of magnitude lower than experimentally observed deformation shear stresses (e.g. $\sim 10^6$ N/m$^2$ in metals). This discrepancy in mechanical strength is explained by the presence of dislocations in materials. The discrepancy in ferroelectrics has primarily been discussed through the recognition that while the simple estimate of intrinsic coercive fields from the Landau–Ginzburg (LG) theory does not account for the presence of domain walls or other defects, real single domain crystals nonetheless possess defect sites where it is easier to nucleate domains. Once a domain nuclei exists, the Miller and Weinreich theory explains the effective lateral motion of pre-existing, atomically sharp domain walls, in terms of the probability of overcoming an energy barrier, $U$, to preferentially nucleate small wedge-shaped domains adjoining the wall. Though not uniquely defined, one can consider the maximum electric field, $E = dU/dP$ required to completely overcome the steepest climb out of the energy well, $U$ versus $P$ (polarization), as an estimate of the intrinsic coercive field. Domain wall pinning at physical defects can also contribute to the experimental coercive fields, which manifests as the threshold field for wall depinning.

In this letter, we explore the theoretical estimate of coercive field from the LG theory in the presence of pre-existing 180° domain walls with finite wall widths. Specifically, we wish to show that a finite polarization gradient at the domain wall can lower the local intrinsic coercive fields adjacent to the wall, thereby facilitating local wall motion.

The problem is treated generally for any ferroelectric with a second-order phase transition, and two possible antiparallel domain states. As specific examples, we consider ferroelectric lithium niobate (LiNbO$_3$) and lithium tantalate (LiTaO$_3$), which are technologically important and typically contain pre-existing domain nuclei in nominally single-crystal, single-domain crystals.

Let us first calculate the theoretical coercive field for 180° domain reversal in these materials. The Ginzburg–Landau–Devonshire free energy per unit volume, $G$, of a ferroelectric with a second order phase transition is given by

$$G = -\frac{\alpha_1}{2} P^2 + \frac{\alpha_2}{4} P^4,$$

where the order parameter is the polarization, $P$. One can calculate the effective $\alpha_1$ and $\alpha_2$ coefficients from the dielectric constant $\varepsilon_{33}$ and the homogeneous spontaneous polarization, $P_s$, as $\alpha_1 = 1/(2\varepsilon_{33})$ and $\alpha_2 = \alpha_1 P_s^2$. These values at room temperature are $\varepsilon_{33} = 43.5 e_o$ and $P_s = 0.55 C/m^2$ for LiTaO$_3$, $\varepsilon_{33} = 30 e_o$, $P_s = 0.75 C/m^2$, for LiNbO$_3$. The equation of state, $E = dG/dP$ defines the theoretical $P$ versus $E$ hysteresis loop. The coercive field $E_c$ is defined as the turning point $(dE/dP)_{E=E_c} = 0$, which determines the polarization $P_c$ at the coercive field as $P_c = \pm \sqrt{\alpha_1/(3\alpha_2)}$. Substituting this value back in the equation of state yields the coercive field $E_c$ as

$$E_c = \pm \frac{2}{3\sqrt{3}} \sqrt{\frac{\alpha_1}{\alpha_2}} = \pm 0.385 \alpha_1 P_s.$$  \hspace{1cm} (2)

Substituting for the values of $\alpha_1$ and $\alpha_2$ in Eq. (2), the intrinsic coercive fields are $E_c \sim 2750$ kV/cm (LiTaO$_3$) and $E_c \sim 5420$ kV/cm (LiNbO$_3$). In contrast, the coercive fields reported in literature for near-stoichiometric LiTaO$_3$ is
The free energy change is calculated as \( \Delta E \), i.e.,

\[
\Delta E = P_f - P_i ,
\]

of a 180° domain wall in LiTaO$_3$ after movement of the wall by an amount \( a \) under the influence of an external field \( E \) in the \( \pm x \) direction. (b) The corresponding polarization energies [Eq. (1)], \( G_i \) and \( G_f \), and \( \Delta G = G_f - G_i \) are also shown. The normalization term \( x_o \) is the domain half width according to Eq. (3).

\[
\Delta P = P_f - P_i ,
\]

\[
P = P_i \tanh(x/x_o) ,
\]

where \( P_i \) is the spontaneous polarization, \( x \) is coordinate normal to the wall and \( 2x_o \) is the characteristic wall width. This polarization, \( P \) and \( \Delta P \), are related to the free energy, \( G \) [from Eq. (1)] is plotted in Fig. 1(a) for LiTaO$_3$. Now we ask the following question: What is the free energy change \( \Delta G \) when such a domain wall moves by one lattice parameter, \( \Delta x = a \), resulting in a change of polarization and energy at every location \( x \) by amounts \( \Delta P = P_f - P_i \) and \( \Delta G = G_f - G_i \) ? (Subscripts \( i \) and \( f \) stand for initial and final states, respectively, as shown in Fig. 1). One can numerically calculate these quantities. On the other hand, if one assumed that \( a/x_o \) is small, then, one can analytically evaluate \( \Delta P = (dP/dx) \Delta x \) from Eq. (3). The corresponding free energy change is calculated as \( \Delta G = (dG/dP) \Delta P \), using Eq. (1) and \( \Delta P \).

This occurs at the wall center \( (x = 0) \). The negative sign reflects the negative slope of \( \Delta G \) versus \( P \) at the wall center under a positive field \( +E \) (see Fig. 1). The coercive field for domain motion can therefore be simplified at the wall center as

\[
E_c' = P_i a / x_o ,
\]

where \( K = P_s a / a \) was determined as 0.368 V for LiTaO$_3$ and 0.726 volts for LiNbO$_3$. Clearly, the coercive field contribution for this type of domain wall motion is inversely proportional to the wall width, \( 2x_o \). Out of curiosity, if we presently ignore other mechanisms, and calculate the values of the equivalent domain wall widths, \( x_o \), required to account for experimentally measured coercive fields in near-stoichiometric lithium niobate and lithium tantalate, for example, from Fig. 1, it is clear that for the wall to move in the \(-x\) direction, there is a positive energy barrier, \( \Delta G \) that the external field, \( +E \) has to overcome, which is less than the original energy barrier, \( G \) for a graded wall. Therefore, the steepest slope of the energy well is small, then, one can analytically evaluate \( \Delta G \) versus \( P \) at the wall center under a positive field \( +E \) (see Fig. 1).

The cross section profile of the piezoresponse signal across the domain wall (i.e., along the black line in the image) is shown on the right-hand side. The imaging voltage of 5 V, 10 kHz was applied using a standard Au-coated Si$_3$N$_4$ cantilever with a spring constant of 0.1 N/m and a resonant frequency of 34 kHz. The probing tip with an apex curvature radius of about 20 nm was in mechanical contact with the sample surface during the measurements (repulsive force regime). The image scan rate was 0.5 Hz.
ute to coercive fields. Taking some these into account, we can therefore write the net experimentally observed coercive fields as,

\[ E_c = E'_c - E_{sc} + E_{\text{defect}}, \]  

where \( E_{sc} \) is the space-charge field, and \( E_{\text{defect}} \) is the bulk dipolar defect field. Surface polarization relaxation\(^\text{15} \) can give rise to a polarization gradient and hence a space-charge layer near the crystal surface as recently observed in LiNbO\(_3\).\(^\text{16,17} \) Even if the space-charge density (charge/area) in this layer is \( \sigma \sim 10^{-2} - 10^{-3} P_s \), the space-charge field, \( E_{sc} \sim \sigma/\varepsilon \), would be of the same order of magnitude as the experimental coercive fields in lithium niobate and tantalate, and will aid in domain wall motion. The dipolar defects, which stabilize domains, such as defect complexes of Ta or Nb antisites and lithium vacancies proposed in recent literature,\(^\text{10} \) will give rise to equivalent defect fields, \( E_{\text{defect}} \),\(^\text{18} \) which tend to increase the coercive fields. As noted in Refs. 10 and 18, the defect field \( E_{\text{defect}} \) is not an existing electric field in the material. Rather, it is a formal equivalent to the energetic difference between the two domain states \( + P_s \) and \( - P_s \), one stabilized by the dipolar defects by an amount of energy \( -E_{\text{defect}} P_s \) and another raised in energy by the same amount. Therefore, a very likely scenario for near-stoichiometric crystals, \( (E_{\text{defect}} \sim 0) \) is that the experimentally measured coercive field, \( E_c \), may be equal to the net sum of the first two terms in Eq. (5) (and perhaps further contributions arising from other types of defects). Since the stoichiometric composition of LiTaO\(_3\) has a coercive field of \( \leq 17 \) kV/cm, the defect field in the congruent composition would be \( \geq 210-17 = 193 \) kV/cm, which clearly dominates the experimentally observed coercive fields (210 kV/cm) in congruent compositions.

The important conclusion of this letter is that, compared with theoretical estimates, the local coercive field in the presence of a polarization gradient at a 180° domain wall is reduced by a factor of \( \sim 0.385 x_o/\lambda \), where \( \lambda \) is the lattice parameter and \( 2x_o \) is the wall width. More generally, one could expect that any significant polarization fluctuation in a ferroelectric crystal, not just limited to a domain wall, would potentially reduce the coercive field for domain reversal in that region. The precise experimental determination of polarization wall width (particularly in the presence of small amounts of nonstoichiometry and under external fields) is central to resolving the issue of theoretical coercive fields in ferroelectric crystals.
