ABSTRACT. Morphological modifications of the first pair of legs in addition to widespread color variations of these legs among males of closely related species have been reported in a variety of spiders. Here, the evidence for sexual dimorphism in male foreleg morphology within wolf spiders (family Lycosidae) is reviewed and shown to occur in a number of species belonging to at least seven genera in five subfamilies: Alopecosa, Hogna, Schizocosa (all Lycosinae) Pirata (Piratinae), Evippa, (Evippinae), Pardosa (Pardosinae) and Artoria (Artoriinae). These modifications, often in combination with distinct dark pigmentation, can be divided into three major groups: leg elongation, segment swelling and exaggerated setation ("brushes"). The latter two occur mainly on the tibial segment of the first leg. The function of these foreleg modifications has been studied most extensively in the genus Schizocosa. Since the courtship displays of all male Schizocosa incorporate a seismic component, foreleg ornamentation (namely pigmentation and associated "brushes") composes only one part of a multimodal courtship display. The function of this foreleg ornamentation appears to vary across closely related Schizocosa species and in some instances involves an interaction with the seismic signaling component. In most instances it appears to play a role in female mate choice and/or mate choice learning. In addition to reviewing lycosid foreleg modifications, we describe a new species of wolf spider, Artoria schizocoides from southwestern Western Australia that possesses sexually dimorphic modifications of the tibia of the first leg. Unique within the Artoriinae, males of this species carry spatulate setae on the ventral side of the tibia of the first leg that differ morphologically from other leg modifications in wolf spiders.

Keywords: Courtship display, sexual dimorphism, sexual selection, secondary sexual traits

Two main evolutionary processes that work independently or in combination are thought to explain sexual dimorphism or the morphological differences between males and females. One category relates morphological differences between males and females to a reduction in intersexual competition for resources (ecological niche partitioning) (Shine 1989; Fairbairn 1997). The second explains sexual dimorphism by differences between the sexes in the relationship between a particular trait and reproductive fitness (sexual selection or differences in reproductive roles) (e.g., Seander 1972; Hedrick & Temeles 1989; Reynolds & Harvey 1994). Sexual selection arises through competition between members of one sex for reproduction with the other sex. Here, dimorphic structures may either be used in direct aggressive encounters with members of the same sex (generally males; intrasexual selection), or used by members of the opposite sex to assess mate quality (generally females; intersexual selection) (Darwin 1871; Andersson 1994).

In wolf spiders, sexual dimorphism is evident in a multitude of forms and most differences between males and females are attributed to differences in reproductive roles. With a few exceptions (e.g., Donacosa merlini Alderweireldt & Jocqué 1991) females are larger than males. In most ground dwelling species, these size differences are mainly explained by a fecundity advantage of larger females (Pren- ter et al. 1997, 1998, 1999). Sexual dimorphism also exists with respect to differences in trophic morphology (i.e., the sizes of che-
licerae and venom glands); these differences have been ascribed to the increased importance of foraging for females rather than an avoidance of intersexual competition for food (Walker & Rypstra 2001, 2002). Across many wolf spider species, especially those with sedentary females, males also possess comparatively longer legs than females. This leg dimorphism is thought to have evolved through an advantage of more mobile males to encounter females occupying permanent burrows (Framenau 2005a). While the above forms of dimorphism refer mainly to differences in body shape or size, dimorphic color patterns to augment body size and condition have also been argued to play an important role in the mating behavior of wolf spiders (Moya-Laranjo et al. 2003).

Dimorphic patterns of foreleg pigmentation appear to be one of the most widespread and conspicuous form of sexual dimorphism among wolf spiders (Framenau, pers. obs.) and these differences in foreleg ornamentation appear to be driven mostly by sexual selection. Male foreleg ornamentation commonly involves extremely dark pigmentation or very distinct light coloration on individual foreleg segments or covering the entire front pair of legs. In some species, males possess an exaggerated form of foreleg ornamentation involving morphological modifications of the first pair of legs. These morphological modifications occur in a variety of forms in most currently recognized subfamilies of wolf spiders. Our study aims to review the evidence for sexual foreleg dimorphism within the spider family Lycosidae by compiling morphological information from the taxonomic literature. In addition, we describe a species with a novel form of male tibial ornamentation—ventral spatulate modified setae. This species, Artoria schizocoides n. sp., belongs to the Australasian/Pacific subfamily Artoriinae and is the only species within this subfamily known to the authors with excessive setation on the first pair of legs.

MORPHOLOGICAL MODIFICATIONS IN THE FIRST LEG OF WOLF SPIDERS

Morphological modifications of the first pair of legs in male wolf spiders belong to three major categories: (1) elongation, (2) swelling and (3) exaggerated setation, the latter two of which are most prevalent on the tibial segment (Table 1).

Elongation.—An elongation of the front pair of legs can be either subtle (e.g., Alopecosa cuneata (Clerck 1757) (Kronestedt 1990) or very conspicuous (e.g., Artoria flavimanana Simon 1909) (Framenau 2002). For example, in the Palaeartic Alopecosa cuneata, the ratio of the length of tibia I to tibia IV is higher than in a related species of similar size, A. pulverulenta (Clerck 1758) (Kronestedt 1990). This elongation of the forelegs has been related to male courtship displays (Kronestedt 1990), as there is direct contact between the forelegs of a male and female A. cuneata in the form of the female grasping the swollen tibial segment of the male with her chelicerae (Kronestedt 1990, for more detail see below). Male Alopecosa taeniata (C. L. Koch 1835) also have longer legs as compared to the closely related A. aculeata (Clerck 1758) (Kronestedt 1990). In this case however, the elongation is not restricted to the forelegs and increased species-specific mobility of males during courtship is suggested to explain this pattern (Kronestedt 1990), although there is currently no experimental evidence to support this hypothesis.

In almost all wolf spiders the fourth pair of legs is the longest, followed by leg I, and then II and III, or less commonly III and II (expressed in the “leg formula”: IV > I > II > III or IV > I > III > II). However, in males of the Australian A. flavimana mentioned above, the front pair of legs is extremely elongated and much longer than the fourth pair of legs. In females of A. flavimana the fourth leg is the longest, similar to both sexes of all other species in this genus (Framenau 2002, 2004, 2005b, also this study). The elongation is not restricted to a single segment as in A. cuneata but concerns all segments. The behavioral mating sequence of A. flavimana is not known and therefore the function of this morphological modification remains unclear. In male orb-weaving spiders, an elongation of the first pair of legs has been argued to be beneficial to avoid sexual cannibalism (Elgar et al. 1990).

Swelling.—The tibia of the first leg of male A. cuneata is not only elongated (see above) but also distinctly swollen (Fig. 1). The swollen segment does not appear to purely serve to exaggerate a visual signal during male
courtship since the cuticle around the tibia is equipped with numerous pores (Kronestedt 1986, 1990; Dahlem et al. 1987). The pores correspond to exocrine glandular units which are composed of a large adenocyte, a long sinuous epicuticular duct and a canal cell among supporting epidermal cells (Juberthie-Jupeau et al. 1990). During courtship, the female has to actively grasp one tibia of the male with her chelicerae before he can mount her. During this grasping it is possible that females are able to assess secretions from the male's gland tissue (Dahlem et al. 1987). A swelling of the tibia of the first leg is also evident in Pirata cantralli Wallace & Exline 1978 and Pardosa vancouveri Emerton 1917 (Dondale & Redner 1990), and described as “slight” for A. pulverulenta (see Dahlem et al. 1987), suggesting a similar morphology and function (Table 1). Scattered pores have also been found on legs of other lycosids, e.g., in Pardosa C. L. Koch 1847, Trochosa C. L. Koch 1847 (Kronestedt 1986), and Acantholycosa Dahl 1908 (Kronestedt & Markusik 2002) and in Xerolycosa miniata (C. L. Koch 1834) (Juberthie-Jupeau et al. 1990).

Color dimorphism and excessive setation (“brushes”).—The most conspicuous sexual dimorphism in wolf spiders involves differences in foreleg pigmentation between the sexes, with males possessing dark pigmentation on particular foreleg segments. In some species this pigmentation is accompanied by the addition of dense brushes of specialized setae. Male pigmentation/brushes are often referred to as secondary sexual ornamentation and are thought to play an important role in reproductive behavior. The function of male foreleg ornamentation has received a great deal of attention within the Nearctic species of the genus Schizocosa where 14 of the 24 described species in North America display foreleg dimorphisms (Stratton 2005). The dimorphisms of some species are considered “slight” (Stratton 2005) and original species descriptions state that the “general structure and color” of females is “essentially as in males” (S. floridana Bryant 1934, S. maxima Dondale & Redner 1978, S. saltatrix (Hentz 1844)). Without considering these species, four North American species remain that possess foreleg pigmentation only: one species with pigmentation on the tibia (S. utzti Stratton 1997) and three species with pigmentation on the femur (S. cespitum Dondale & Redner 1978, S. communis (Emerton 1885), S. retrorsa (Banks 1911)) (Stratton 2005). Seven North American species are described as having brushes on their foreleg tibia: four species with tibia I brushes and pigmentation (S. au-lonia Dondale 1969, S. bilineata (Emerton 1885), S. salsa Barnes 1953, S. segregata Gertsch & Wallace 1937; Table 1) and three species complexes with tibia I brushes and pigmentation in addition to femur I pigmentation (S. crassipes (Walckenaer 1837) (Fig. 2), S. ocreata (Hentz 1844), S. stridulans (Stratton 1984; Table 1) (Stratton 2005).

Based upon a morphological phylogeny of the North American species, male foreleg ornamentation is suggested to have evolved independently five to six times and to have been subsequently lost two or three times (Stratton 2005).

All known Schizocosa species possess a seismic component to their courtship display and seismic signaling is believed to be ancestral in this genus (Stratton 2005). A survey across wolf spiders found male foreleg ornamentation to be associated with the presence of active leg-waving displays, resulting in the suggestion that all ornamented species possess multimodal courtship signaling (seismic and visual) (Hebets & Uetz 2000). In signal isolation experiments across numerous Schizocosa species, which vary in presence or absence and type of foreleg ornamentation, females of only brush-legged species responded to isolated conspecific visual signals while females from all species responded strongly to conspecific male seismic signals (three monomorphic species: S. duplex Chamberlin 1925 (Hebets & Uetz 1999); S. rovneri Uetz & Dondale 1979 (Scheffer et al. 1996); S. sal-tatrix (Uetz & Roberts 2002); one pigmentation only species: S. utzti (Hebets & Uetz 1999); and three brush-legged species: S. crassipes, S. stridulans (Hebets & Uetz 1999), and S. ocreata (Scheffer et al. 1996); summarized in Uetz & Roberts 2002; Hebets & Papaj 2005). These results suggest that while seismic signaling is important across all species, visual signaling is putatively important in species with strong sexual foreleg dimorphism.

The foreleg brushes in S. ocreata are known to be condition-dependent (Uetz et al. 2002) and in the absence of seismic signals,

females have decreased receptivity to males with shaved versus intact brushes (Scheffer et al. 1996) as well as to males with smaller brushes (McClintock & Uetz 1996). Curiously, female receptivity did not vary with male ornamentation in experiments using the video playback technique, with courtship sequences involving manipulated male ornamentation (“control” video vs “no ornamentation” video vs “enhanced brushes” video; McClintock...
Figures 1–4.—Photographs of ornamented tibia on the first pair of legs in male wolf spiders. 1. Tibial swelling in male *Alopecosa cuneata* from Marburg, Germany (WAM T56440). 2. Tibial setae in male *Schizocosa cf. crassipes* from Oxford Campus, University of Mississippi, USA (WAM T56106). 3. & Uetz 1996). Live trials involving males with shaved brushes versus intact brushes also did not result in mating frequency differences (Scheffer et al. 1996). Ultimately, tibia I brushes in *S. ocreata* are thought to increase courtship signal efficacy in a seismically unpredictable, heterogeneous signaling environment (Scheffer et al. 1996). A pre-existing bias in females for foreleg brushes was previously suggested to have played a role in the evolution of *S. ocreata* foreleg ornamentation (McClintock & Uetz 1996); however a recent morphological phylogeny suggests that the formerly observed preference of females from a non-ornamented species (*S. rovneri*, McClintock & Uetz 1996) for males with brushes is a retained behavioral trait (Stratton 2005).

In experiments using the video playback technique in the absence of seismic signals, females of a second brush-legged species, *S. crassipes* showed a marginally significant preference for pigmented males over non-ornamented males (Hebets & Uetz 2000), suggesting a role of brushes in female mate choice. Females of a third brush-legged species, *S. stridulans*, were significantly more receptive to video playbacks of males with enhanced brushes as compared to males with pigmentation removed (Hebets & Uetz 2000), clearly demonstrating a role of foreleg ornamentation in female mate choice. However, in a follow-up study using the same video playbacks in conjunction with seismic courtship signals from live males, female *S. stridulans* did not distinguish among visual stimuli (Hebets unpublished data), suggesting that visual signals are important only in the absence of seismic information for *S. stridulans*. Interestingly, the exact opposite pattern was ob-
served in a pigmentation only species (S. uetzii), where females did not distinguish among visual stimuli using video playbacks in the absence of a seismic signal (Hebets & Uetz 2000). However, with the addition of a conspecific seismic signal, females preferred males with exaggerated ornamentation (“brushes added” vs “no ornamentation” video, Hebets 2005). Follow-up experiments with S. uetzii suggest that the seismic and visual signals interact such that the seismic signal alters a female’s visual attention (Hebets 2005). A recent study using live manipulated males questions the significance of this intersignal interaction for inexperienced females (Hebets et al. 2006) but suggests that the pigmentation observed in S. uetzii may be important in female mate choice learning. The importance of early experience on adult mate choice was previously demonstrated in S. uetzii as females were more likely to mate with a male of a familiar versus unfamiliar foreleg pattern (Hebets 2003). In the same study, females were more likely to cannibalize males possessing an unfamiliar foreleg pattern, suggesting strong selection on male ornamentation, maturation time, and/or male behavior (Hebets 2003).

While the tibia I brushes of many Schizocosa species have attracted much scientific attention, such morphological modifications are also found in other genera within the subfamily Lycosinae Sundevall 1833 (sensu Dondale 1986) (Table 1). Alopecosa barbipes (Sundevall 1833), for example, was listed as junior synonym of A. accentuata (Latreille 1817) by Lugetti & Tongiorgi (1969), and the presence (A. barbipes) or absence (A. accentuata) of tibial brushes was previously regarded as intraspecific variation. Subsequently, A. barbipes was removed from this synonymy based on morphological, behavioral and ecological differences (Dahlem et al. 1987; Cordes & Helversen 1990) and recent molecular studies confirmed the identity of A. barbipes as a separate species (Vink & Mitchell 2002). Bushy setae on the first tibia of males can also be found in other subfamilies of wolf spiders (Table 1). Two species of Evippomma Roewer 1959, E. plumipes (Lessert 1936) and E. squamulatum (Simon 1898), carry a striking fringe of black setae on the ventral and dorsal side of the first tibia (Fig. 3; also Alderweireldt 1992). The males of Artoria schizocoides n. sp. carry unique spatulate setae on the ventral side of their first tibia (Fig. 4; see also below). Other segments in addition to the tibiae may carry conspicuous modified setae. The males of Pirata cantralli Wallace & Exline 1978 have long curly setae on the metatarsi of the front legs (Dondale & Redner 1990). Some species of Pardosa C.L. Koch 1847 have conspicuous setae on the tarsi, metatarsi and tibia (Tongiorgi 1966a, b). Although a similar function as in Schizocosa is likely, there is no experimental evidence on the significance of these structures in these species.

The excessive setation observed in some wolf spider species may not function solely in a reproductive context. For example, in some Australian species currently listed in Hogna Simon 1885 males possess very fine, long setae around the whole circumference of the front tibia (Table 1; also Framenau et al. 2006). In contrast to the setation in Alopecosa, Schizocosa, Evippomma, Pardosa and Artoria, these setae are less conspicuous in live specimens and thus a role in visual signaling appears doubtful. When disturbed, males run with their front legs raised high in the air, suggesting a putative role in sensory perception and information gathering (Framenau pers. obs.). However, there is currently no experimental evidence for this function and detailed studies of setae structure may elucidate a putative role in sensory perception.

In summary, morphological modifications of the front legs in wolf spiders can be found in most of the currently recognized subfamilies (Dondale 1986; Zyuzin 1993; Framenau 2007). They are generally absent in the larger, burrowing and mainly nocturnal species, for example in the genera Lycosa Latreille 1804 (Palaearctic) (e.g., Orta-Orcaña et al. 1996), Geolycosa Montgomery 1904 (Nearctic, Palaearctic), Tasmanicosa Roewer 1959 and Venatrix Roewer 1960 (e.g., Cutler 2002) (both Australian). It appears that foreleg modifications are more common in smaller, diurnal species, which strengthens their putative function in visual signaling. Although numerous Schizocosa species have been the focus of elegant studies regarding female mate choice and the evolution of male foreleg dimorphism/ornamentation, much remains to be learned. Foreleg ornamentation appears to function in different ways even among closely related Schizocosa species, suggesting that it may be
difficult to make broad generalizations about the evolution of sexual dimorphisms in wolf spiders. However, studies of similar morphological modifications in other wolf spider taxa are needed and will certainly add to our general understanding of the evolution of sexual foreleg dimorphism.

**TAXONOMY**

*Artoria* is an Australasian genus, currently with 23 representatives from the Philippines in the North to New Zealand in the South (Framenau 2002, 2004, 2005b; Framenau et al. 2006). However, a large number of unnamed species have been found in Australian and Pacific collections and the genus is believed to include more than 80 species in Australia alone (Framenau, personal observation). *Artoria* is characterized by a male pedipalp with a bifurcate or spoon-shaped apically directed tegular (= median) apophysis with a narrow base (Framenau 2002). Recent molecular studies suggest that *Artoria* as currently defined may not represent a monophyletic group (Murphy et al. 2006), however all currently described *Artoria* species belong to the Australasian/Pacific subfamily Artoriinae that received very good nodal support (Vink et al. 2002; Murphy et al. 2006). This subfamily can easily be identified by the presence of a basoembsilic apophysis in the male pedipalp (Framenau 2007). Other genera within this clade include *Anoteropsis* L. Koch 1877 and *Notocosa* Vink 2002 (Vink 2002), *Tetranychus* Roewer 1960 (Framenau et al. 2006) and *Diafragmata* Roewer 1960 (Framenau 2006).

**METHODS**

Descriptions are based on specimens preserved in 70% EtOH. A female epigynum was prepared for examination by submersion in lactic acid for 24 h. Scanning electron microscope (SEM) images were taken with a Carl Zeiss Leo 1420VP (Oberkochen, Germany) after fixing the respective spider parts in Karnovsky’s fixative (Sheehan & Hrapchak 1980) and osmic acid. For clarity, the illustrations of genitalia omit the setae. The morphological nomenclature follows Framenau (2002). All material investigated is lodged at the Western Australian Museum, Perth, Australia (WAM).

**Abbreviations.**—Measurements are in mm: total body length (TL), carapace length (CL) and width (CW), abdomen length (AL) and width (AW). Eyes: anterior row of eyes (AE), anterior median (AME), anterior lateral (ALE), posterior row of eyes (PE), posterior median (PME), posterior lateral (PLE).

*Artoria schizocoides* new species

Figs. 4–11

**Types examined.**—Holotype male, Australia, Western Australia: Bluff Knoll, Stirling Range National Park, 34°23’S, 118°15’E, 19 March 1996, S. Barrett, site 230, wet pitfall trap (WAM T53800). Paratypes: 1 male, 4 females, Bluff Knoll, Stirling Range National Park, Western Australia, Australia (34°22’/56’S, 118°14’/55’E), 7 September 1995, S. Barrett, site 214, 900m, pitfall traps (WAM T53799, T53875).

**Other material examined.**—AUSTRALIA: Western Australia: 1 δ, 1 †, Alcoa mine, NE Jarrahdale, 32°17’S, 116°08’E (WAM T44717); 2 δ, 1 †, Alcoa mine site & forest, N and NW Jarrahdale, 34°54’S, 117°55’E (WAM 97/ 583–4); 51 δ, 10 †, Dwellingup, 32°43’S, 116°04’E (WAM T42134, T53762–76); 1 δ, Forth River, 45 km SE Northcliffe, 34°50’S, 116°26’E (WAM T65102); 1 δ, 1 †, Jarrahdale, 32°20’S, 116°03’E (WAM T55764–5); 7 δ, 2 †, Manjimup, 32°15’S, 116°09’E (WAM T53777–9); 15 δ, 4 †, Mt. Cooke, 32°25’S, 116°18’E (WAM 98/2168, T53760–2, T62483, T65097; T65595); 60 δ, 3 †, Mt. Lindesay, 34°50’/30’S, 117°18’/21’E (WAM T53607–10); 3 δ, 1 †, Porongurup National Park, 34°40’/56’S, 117°51’/59’E (WAM T53805); 1 δ, Quinninup, nearby, 34°26’S, 116°15’E (WAM T65093); 21 δ, 4 †, Stirling Range National Park, Bluff Knoll, 34°23’S, 118°15’E (WAM T53799, 53801-3); 3 †, 4 juv., Stirling Range National Park, 12 km S Bluff Knoll, 34°29’E, 116°15’E (WAM T55578); 1 δ, Stirling Range National Park, Mondurup Peak, 34°24’/18’S, 117°48’/44’E (WAM T53804); 29 δ, 14 †, 7 juveniles, Stirling Range National Park, S face of Pyongrup Peak, 34°22’/17’S, 118°19’/20’E (WAM T53761); 1 δ, 1 †, Stirling Range National Park, The Cascades, 34°22’/29’S, 118°14’/17’T (WAM T53832); 1 δ, Sues Bridge, 50 km SW Nannup, 34°05’S, 115°40’E (WAM T65136).

**Etymology.**—The specific name is an adjective in apposition and refers to the wolf spider genus *Schizoccosa*, the best studied genus in relation to the behavioral significance of brushed front legs in males.

**Diagnosis.**—*Artoria schizocoides* is the
only Artoria species known to the authors of which males have spatulate setae on the ventral side of the tibia of the first leg. The epigynum of females remotely resembles that of A. cingulipes, however, A. schizocoides is much smaller and darker in colorations.

Description.—Male (holotype WAM T53800): Carapace: dorsal line straight in lateral view, head flanks vertical; carapace very dark brown; brown median band, as wide as PLE anteriorly but narrowing and brightening posteriorly, distinctly yellow behind fovea; indistinct brown submarginal bands; head region very dark brown, base of eyes black; dark gray radial pattern; scarce cover of short white setae, slightly denser in head region; few longer bristles in head region; one very long bristle between AME, two long bristles between ALE; AE strongly procurred. Sternum: yellow; gray pigmentation; sparsely covered with brown bristles, which are longer towards margins. Labium: brown, front end truncated and white. Chelicerae: dark brown, falcis yellow; few long bristles in basal half; three retromarginal teeth, with the basal smallest, three promarginal teeth, with the medium largest. Pedipalp (Figs. 5–7, 10): cymbium dorsally with scopulate setae in apical half; apical tip of tegular apophysis bent ventrally, small protrusion on its apical edge; embolus reaches to about three quarters length of sclerotized groove of terminal apophysis (Fig. 7). Abdomen: dark olive gray; indistinct brown lanceolate heart mark in anterior half; mottled
Figure 10.—*Artoria schizocoides*; pedipalp of male from Alcoa mine site and forest, N and NW of Jarrahdale, Western Australia (WAM 97/584) in ventral view (SEM).

with brown spots; sparsely covered with white and, less dense, black setae; venter yellowish gray; three indistinct gray longitudinal bands; spinnerets with brown pigmentation. Legs: leg formula IV > I > III > II; femur I dark gray, femora II–IV dorsally brown with three indistinct dark annulations, ventrally yellow; tibia I black, ventrally with dense brush of spatulate setae (Fig. 4), tibiae II–IV light brown with indistinct annulations; metatarsus I yellow with contrasting black base, metatarsi II–IV brown with indistinct annulations; tarsus I yellow, tarsi II–IV brown; spinination of leg I: Femur: 3 dorsal, 1 apicoprolateral; tibia: 3 ventral pairs, 2 prolateral; metatarsus: 3 ventral pairs; 1 apicoventral.

**Female** (based on paratype WAM T53875): Carapace and sternum: coloration and setae arrangement as male but carapace slightly lighter; AE strongly procurved. Labium: brown, front end truncated and white. Chelicerae: light brown, claws dark brown, brown bristles medially; dentition as male. Abdomen: dorsally uniformly olive-gray; indistinct lighter heartmark in anterior half and two light patches in posterior half; covered with short brown setae; venter olive-gray with irregular small yellow spots laterally and in two longitudinal lines medially; spinnerets yellow. Epigynum, ventral view (Fig. 8): Simple and round sclerotized ring, white centrally. Epigynum, dorsal view (Fig. 9): Large kidney-shaped complex of spermathecae and copulatory ducts. Legs: Leg formula IV > II > I > III; all segments light brown with distinct annulations; spinination of leg I: Femur: 3 dorsal, 1 apicoprolateral; tibia: 2 ventral pairs, 1 apicoprolateral; metatarsus: 3 ventral pairs.

**Measurements**: male holotype WAM T53800 (female paratype WAM T53875): TL 3.24 (5.43), CL 1.88 (2.11), CW 1.30 (1.53). Eyes: AME 0.06 (0.06), ALE 0.06 (0.06), PME 0.26 (0.26), PLE 0.20 (0.20). Row of eyes: AE 0.35 (0.43), PME 0.69 (0.75), PLE 0.75 (0.87). Sternum (length/width) 0.87/0.81 (0.93/0.81). Labium (length/width) 0.23/0.20 (0.35/0.29). AL 1.56 (3.04), AW 0.98 (2.31). Legs: Lengths of segments (femur + patella/tibia + metatarsus + tarsus = total length): Pedipalp 0.69 + 0.61 + 0.66 = 1.96, I 1.36 + 1.62 + 0.95 + 0.58 = 4.51, II 1.27 + 1.45 + 0.95 + 0.58 = 4.25, III 1.19 + 1.30 + 1.13 + 0.66 = 4.28, IV 1.59 + 1.13 + 1.88 + 1.13 = 6.42 (Pedipalp 0.67 + 0.75 + 0.52 = 1.94, I 1.30 + 1.59 + 0.93 + 0.58 = 4.40, II 1.27 + 1.50 + 1.01 + 0.55 = 4.33,
Variation: males (females) (range, mean ± s.d.): TL 3.32–3.90, 3.49 ± 0.22; CL 1.73–1.96, 1.79 ± 0.09; CW 1.21–1.39, 1.28 ± 0.05; n = 10 (TL 3.90–5.64, 4.64 ± 0.53; CL 1.79–2.17, 1.99 ± 0.17; CW 1.27–1.50, 1.36 ± 0.09; n = 10).

Distribution.—Southwest Western Australia (Fig. 11).

Natural history.—Artoria schizocoides appears to mature in winter. Most records of adult females and males are from a period between June and September, with occasional reports from October and November. The species seems to prefer dry to moderately moist forests in mountainous regions.

ACKNOWLEDGMENTS

We are indebted to Gail Stratton and Ansie Dippenaar-Schoeman who provided material for this study. Young-Bo Lee and An-Ja Ko (National Institute of Agricultural Science, Seoul, Korea) took the SEM photographs. Torbjörn Kronestedt provided helpful and constructive comments on an earlier draft of this manuscript. Julianne Waldock initially directed the senior author’s attention to the small brush-legged A. schizocoides in the collection of the WAM. This investigation forms part of a revision of Australian wolf spiders funded by the Australian Biological Resources Study (ABRS) to Mark Harvey (Western Australian Museum) and Andy Austin (University of Adelaide).
