SUMMARY

Seventeen variables measured before breeding and three measures of reproduction were taken on 339 purebred Duroc, Hampshire and Yorkshire gilts and 192 two-breed cross gilts resulting from matings among these breeds. Eight principal components accounted for 90% of the dependency structure existing among the 17 traits measured before breeding. Two principal components accounted for 97% of the dependency structure existing among the three reproductive traits.

The first principal component (PC11) from the prebreeding traits was a general measure of growth ability and accounted for 28% of the variation in the 17 measurements. The second principal component (PC12) contrasted slow growing gilts from fast growing litters with fast growing gilts from slow growing litters and accounted for 14.5% of the total variation. The heritability for PC11 was .71 and indicates that selection for gilts with high values for PC11 (above average growth) would be very successful.

The first principal component (PC21) from the reproductive traits contrasted gilts having large numbers of embryos and good embryo survival with gilts having few embryos and poor embryo survival. The second principal component (PC22) contrasted gilts having high ovulation rates and poor embryo survival with gilts having low ovulation rates and good embryo survival. PC21 and PC22 accounted for 57.2% and 39.5%, respectively, of the dependency structure existing between ovulation rate, embryo numbers and embryo survival rate.

Based on the correlations of principal components from growth traits with principal components from reproductive traits, the following conclusions were made: If litter averages are indications of the genetic potential of a gilt selected from that litter, then gilts with a high genetic potential (good litter averages) that exhibit that potential (good individual performance) have high PC11 values and are genetically superior for ovulation rate but are genetically inferior for embryo survival rates (high PC22 values). Gilts with a good genetic potential (good litter average) that fail to meet that potential (poor individual performance) have high PC12 values and are genetically inferior for ovulation rate but genetically superior for embryo survival rate (low PC22 values).

(Key Words: Growth, Reproduction, Gilts, Principal Components.)

INTRODUCTION

Multivariate techniques, other than path coefficients and multiple regression, have been used only to a very limited extent in the field of animal science. Principal component analysis is a multivariate technique for reducing $p$ correlated measurement variables to a smaller set of statistically independent linear combinations of the original measurements. This technique attempts to find linear compounds of the original variables which can account for the dependency structure existing among the original measurements. This technique was used by Wright (1932) and more recently by Carpenter et al. (1971) and Brown et al. (1973).

The primary objective of this study was to
use principal components as a means of evaluating
the relationship of prebreeding traits with
reproductive traits. Because of the nature of a
principal component analysis there were two
intermediate objectives or steps: to evaluate the
relationships among the prebreeding traits and
to evaluate the relationships among the repro-
ductive traits.

**MATERIALS AND METHODS**

This study included the records of 339
purebred Duroc, Hampshire and Yorkshire gilts
and 192 two-breed cross gilts resulting from
matings among the three breeds. The method of
handling these gilts was described in detail by
Young et al. (1977). The prebreeding traits
evaluated were: the size of litter the gilt was
born in (NB) and weaned in (NW); her birth
weight (BW), weaning weight (WW), average
daily gain (ADG) and age at 100 kg (AGE); the
average of the litter from which the gilt came
for birth weight (LBW), weaning weight
(LWW), average daily gain (LADG) and age at
100 kg (LAGE); the deviation of the gilt’s
record from the litter average for birth weight
(BWD), weaning weight (WWD), average daily
gain (ADGD) and age at 100 kg (AGED); as
well as breeding age (BRAGE), breeding weight
(BRWT) and days from 100 kg to breeding
(DAYS). The reproductive traits measured
were: number of corpora iutea (CL), number of
embryos (EMB) and number of corpora lutea
per embryo (CL/E). The phenotypic and ge-
netic correlations among all traits were reported
by Young et al. (1977). The phenotypic corre-
lation matrix previously reported served as
input data for the principal component analy-

For a more detailed and technical discussion
of principal component analyses see Anderson
(1958), Morrison (1967) and Overall and Klett
(1971). Brown et al. (1973) provides an exam-
ple of the interpretation of principal compo-
nents. The correlation matrix and standardized
varies are normally used in the calculation of
principal components when the traits measured
are in different units or are largely different in
magnitude. Principal component analysis is a
method for reducing p correlated variables to a
smaller set of statistically independent linear
combinations of the original measurements
which have unique properties. The first princi-
pal component is that weighted combination of
the several original variables which accounts for
a maximum amount of the total variation
represented in the complete set of original
variables. The rth principal component is that
weighted combination uncorrelated with the
first r-1 principal components which accounts
for a maximum amount of the remaining
variation among the original variables (Overall
and Klett, 1971).

The magnitude and sign of the coefficients
within a given component determines the im-
portance and grouping, respectively, of the jth
measurement within that component (Brown et
al., 1973). Within a component, measurements
that are weighted by large coefficients are more
important than those weighted with small
coefficients. Within a component, measure-
ments whose coefficients have the same sign are
grouped together and contrasted against the
group of opposite sign.

Principal components were obtained sepa-
rately for the traits measured before breeding
and for the reproductive traits. In this study, it
was decided, prior to analysis, to calculate
enough principal components to account for at
least 90% of the total variation in the depend-
ency structure of the original response variates.
A value for each principal component was
considered as a new trait. Using the paternal half-sib method,
genetic and phenotypic correlations between
principal components and of principal compo-
nents with the original variates of the opposite
group were calculated. Heritability estimates
were also calculated for the principal compo-
nents.

The traits measured before breeding were
denoted as group 1 and the reproductive traits
were denoted as group 2. The jth principal
component from group i will be denoted as
PCij.

**RESULTS AND DISCUSSION**

**Principal Components for Prebreeding
Traits.** The principal components obtained for
traits measured before breeding are presented in
table 1. Ignoring the near zero coefficients for
NB and NW, the coefficients for all measure-
ments in the first principal component (PC11)
are fairly similar in magnitude. However, except
for one character, the coefficient for the gilt’s
individual value is slightly greater than the
coefficient for the litter average which in turn is
slightly greater than the coefficient for the gilt’s
development from litter average. This indicates that

The first principal component was interpreted as a general measure of growth ability. Gilts with large values for PC11 were from litters which exhibited good growth at all ages while the gilt's own record was also good and even above litter average. Basically, this component contrasts slow growing gilts from slow growing litters with fast growing gilts from fast growing litters. It is somewhat surprising that this basic contrast did not account for more than 28% of the variation among the original variates. Similar values for this component do not necessarily mean similar growth patterns. For example, assume two gilts have exactly the same measurements for all traits except that the first gilt was one standard deviation above average for BW but average for ADG and the second gilt was average for BW but was .68 of a standard deviation above average for ADG. Since all measurements are standardized, these gilts will have the same value for PC11 but will have different growth patterns.

The second principal component (PC12) contrasts the gilt's individual performance with the average performance of the litter she came from. For every character, the coefficient for the deviation of the gilt's performance from litter average has the opposite sign as the coefficient for the litter average. This component contrasts slow growing gilts from small, fast growing litters with fast growing gilts from large, slow growing litters. This component accounted for 14.5% of the variation among the original variates.

Gilts with large values for the third principal component (PC13) came from large litters where the pigs had low birth weights and low weaning weights with the gilt's own record being below litter average for these traits; however, the litter grew well in the feedlot and the gilt was above litter average for growth and age at 100 kg and was heavier and older at breeding. This component contrasts gilts which came from large litters and got off to a poor start due to competition in the large litter but grew well in the feedlot with gilts which came from small litters and got off to a good start but their performance declined in the feedlot.

The fourth principal component (PC14) gave very little weight to NB or NW and accounted for only 9.0% of the variation among the original variates. Gilts with large values for this component came from litters with high average birth weights with the gilt's birth weight being above litter average, but as time passes the litter's performance deteriorates to below average and the gilt's performance deteriorates even faster so that she is below litter average for average daily gain, has more days from 100 kg to breeding and is older and heavier at breeding.

The fifth principal component (PC15) gives considerable weight to NB and NW and accounts for 8.4% of the total variation. Gilts with high values for PC15 came from large
litters at birth and weaning where the pigs had large birth weights and weaning weights but poor average daily gains with the gilt being above litter average for birth and weaning weights and below litter average for average daily gain and also young and light in weight at breeding. The above average performance of these gilts before weaning may result from the superior maternal ability of their dams. This component contrasts gilts which are from large litters and get off to a good start but slow down in the feedlot with gilts from small litters that get off to a poor start but do well in the feedlot.

Similar interpretations can be developed for PC16, PC17 and PC18. Because they account for so little of the total variation and in order to conserve space, this will be left to the reader.

Principal Components for Reproductive Traits. The principal components derived for the three reproductive traits are presented in table 2. Two of the three possible principal components accounted for almost 97% of the generalized variance existing among these three variables.

The first principal component for this group (PC21) explained 57% of the total variation. This component gives relatively little weight to ovulation rate and, in general, it contrasts gilts having large numbers of embryos and good embryo survival rates with gilts having few embryos and poor embryo survival rates. The second principal component (PC22) gives relatively little weight to embryo numbers and contrasts gilts having high ovulation rates and poor embryo survival rates with gilts having low ovulation rates but good embryo survival rates. Embryo survival was measured as number of corpora lutea per embryo. Low values for this trait indicate good embryo survival. These two basic contrasts explain most of the dependency structure existing between ovulation rate, number of embryos and embryo survival rate.

Heritability Estimates. The heritability estimates and standard errors for all principal components are presented in table 3. The sire component of variance was negative for PC17 and PC21 resulting in negative estimates of heritability for these components.

The heritability estimates for PC12, PC14 and PC18 were not large or significant when compared to their standard errors. PC11, PC13 and PC16 had heritabilities that were greater than .70 and significant. The component which would seem to describe the most desirable gilt from a growth standpoint would be PC11. Thus, the high heritability found for this component, indicates that selection for gilts with high values for PC11 would be very successful. The heritabilities of PC15 and PC22 were around .50 and significant.

Genetic and Phenotypic Correlations. The phenotypic ($r_p$) and genetic ($r_g$) correlations of variables in group 1 with principal components from group 2 are reported in table 4. The sire component of variance was negative for PC21 thus preventing the estimation of the genetic correlations for this trait. Genetic correlations of WW and AGE with PC22 were large ($|r_g| > .60$). Genetically, PC22 was moderately correlated with ADG, ($r_g = .51$) and lowly correlated with LBW, NW, LWW, BRAGE, BRWT and DAYS. This suggests that selection of gilts with genetic ability for good growth, especially for good growth rate in the feedlot, will result in gilts with genetic ability for high ovulation rate but poor embryo survival rate. The phenotypic correlations of variables in group 1 with principal components from group 2 were small. Only one of the 34 phenotypic

Sign of the covariance.

The phenotypic and genetic correlations of variables in group 2 with principal components from group 1 are presented in Table 5. Genetic correlations for EMB could not be calculated because of the negative sire component of variance found for this trait. Genetic correlations for PC18 were considerably greater than one and reflect the very small sire component of variance found for that trait. PC11 was highly and favorably correlated, genetically, with CL (rg = 1.05) but not CL/E (rg = .18). The genetic correlations of PC12 with CL and CL/E were - .86 and - .81, respectively. Gilts with high values for PC11 exhibited good performance at all stages of growth while gilts with high values for PC12 were poor performing gilts from good performing litters. Litter averages should be some indication of genetic potential for a gilt selected from that litter. The results seem to suggest that gilts which have the genetic potential for good growth (high litter average) but fail to meet that potential (poor individual performance) are genetically superior for PC12 and embryo survival rate but are genetically inferior for ovulation rate. All phenotypic correlations of variables in group 2 with principal components from group 1 were very small and only the correlation of .21 between PC11 and CL was significant.

The phenotypic and genetic correlations of principal components from group 1 with principal components from group 2 are presented in Table 6. Again, genetic correlations for PC21 could not be calculated due to the negative sire component of variance found for this trait. The replacement gilts should be genetically superior for growth but should be developed slower than are slaughter pigs.

*a Sign of the covariance.

This suggests that replacement gilts should be genetically superior for growth but they should be grown out more slowly than slaughter pigs are grown out. This may suggest new management practices for replacement gilts. It may be advantageous for a commercial producer to select replacement gilts which are heavy at birth and weaning and are from large litters. Rather than full feeding, it may be better to reduce growth rate by limiting feed intake from weaning to breeding but raise them to normal breeding weights. Other evidence for this system has been presented by Aherne (1975). Gilts fed ad libitum from 45 kg to breeding farrowed 1.2 fewer pigs and weaned one less pig than gilts which were fed at a level of 85% of the ad libitum intake over the same period.

In general, these data indicate that there are some fairly large genetic correlations between growth measures and reproductive measures. However, the phenotypic correlations between growth and reproduction are small due to large environmental correlations of opposite sign.
