(Received 16 August 1984; accepted for publication 30 October 1984)

A common field distortion triggered spark gap utilizing geometric field enhancement at sharp edges usually operates in a cascade mode via the trigger electrode. A new trigger concept is proposed allowing strong field enhancement and direct breakdown between the two main electrodes. A test setup was designed to prove the feasibility of this concept. Experimental results on delay and jitter depending on percent breakdown voltage are presented. Best results achieved are a delay of 9 ns and a jitter of 2 ns at a self-breakdown voltage of 15 kV.

I. INTRODUCTION AND TRIGGER CONCEPT

Spark gaps using field distortion triggering are initially designed to provide hold-off voltage without trigger, and a trigger electrode shaped and located on an equipotential surface in the gap is then added. Triggering is accomplished by abruptly changing the potential of this electrode, thereby increasing the field between the trigger electrode and one of the gap electrodes. A typical example is the three electrode gap with a blade as a midplane trigger electrode located approximately half way between the main electrodes. In the hold-off state the blade is in the plane of an equipotential and no field enhancement is generated at the edge of the blade. By changing the potential of the trigger electrode a very strong field enhancement at the edge can be produced. Since the maximum field enhancement occurs at the trigger electrode, however, the switch operates usually in a cascade mode in which the gap between one electrode and the trigger electrode is first closed (initiated by the trigger pulse) and then the second half of the gap is closed by the voltage across the switch.

To allow for geometrically enhanced field distortion and still to avoid cascade breakdown, field enhancement at an edge of one of the main electrodes can be used. This edge, however, must also be shielded in the hold-off state of the gap. A schematic diagram of a spark gap based on this concept is shown in Fig. 1. In this device the trigger electrode is used to shape the electric field intensity in the gap in both the hold-off state and the triggering state. In the hold-off state the trigger electrode is kept at the same potential as electrode (1) and its surface towards the gap is shaped to minimize the geometric field enhancement effects at the main gap electrode, thereby maximizing the hold-off voltage. In the triggering state the potential of the trigger electrode is moved towards the potential of electrode (2). The trigger electrode subsequently serves to enhance the field, providing improved triggering, in two ways: moving the equipotential toward one gap electrode, and simultaneously turning on the geometric field enhancement. Such a trigger concept combines several advantages:

(1) Geometrically enhanced field distortion can be utilized.

(2) The strongest field enhancement occurs at one of the main electrodes, and breakdown, without cascading via the trigger electrode, is possible.

(3) Since the electrode can be shaped without changing the hold-off performance, the field enhancement at a main electrode can be much larger than in common field distortion triggering.

(4) Shape and surface conditions of this main electrode do not determine the hold-off performance of the gap, making the gap more independent of erosion. This concept would have to be applied to both main electrodes for protection of both.

II. TEST SETUP

The experimental setup used to test this trigger concept is shown in Fig. 2. A parallel plane line was used as charging and transmission line (total impedance ~ 12.5 Ω). The switch consisted of eight individual gaps. The upper conductor of the lines was divided into eight individual stripes to provide for transit time insulation of the individual gaps (im-
pedance/stripes \approx 100 \Omega \), the time constant for the transit time insulation could be varied in the range of 0–5 ns by moving metal bars connecting the individual transmission and charging lines.

Two different electrode configurations were used as shown in Fig. 3. The configuration (A) uses one triangular shaped main electrode (1) with a pair of two rods as trigger electrodes and one rounded main electrode (2), while the configuration (B) uses a symmetric configuration with two triangular main electrodes. The trigger electrodes in any case were pairs of rods triggering all eight individual gaps at the same time as demonstrated for the configuration (B) in Fig. 4. Bare stainless steel bars as well as bars covered with a dielectric material (glass tubes or epoxy) or with a resistive material (graphite-filled epoxy) have been used.

The trigger circuits are shown in Fig. 5. The trigger pulse was provided by a secondary gap which was operated in the self-breakdown mode and the breakdown voltage was adjusted through changing the secondary gap electrode separation. In the hold-off state the trigger electrodes are at the potential of the adjacent main electrode. When the secondary gap fires the potential of the trigger electrode is driven towards the potential of the opposite electrode.

For the circuits (A), (B), and (C) the full charging voltage of the line can be applied to the trigger electrode, while for the circuit (D) both trigger electrodes potentials move towards the midplane potential of the gap.

III. EXPERIMENTAL RESULTS

The experiments performed concentrated on the spark gap performance with respect to delay and jitter depending on the applied voltage in percent of the breakdown voltage. The first experiments to determine the optimum type of trigger electrode and polarity were performed with an electrode geometry as shown in Fig. 3(a) and a circuit as shown in Fig. 5(a). Although the system could be triggered with either polarity, clearly better trigger results were obtained with the electrode (1) being at positive potential and the trigger electrode being driven towards a negative potential. Triggering
was possible with all types of trigger electrodes used. Bare metal rods as trigger electrodes had the disadvantage that a very precise symmetric alignment was necessary to avoid arcs between the trigger electrode and the main electrode. The best results were obtained with electrodes covered with a dielectric layer (glass or epoxy). Since the system performance did not depend on repetition rate (10^{-2}–1 Hz) surface charges on the surface of the dielectric seemed not to affect the performance of the trigger method at these low repetition rates. Surface charges could be eliminated with resistive layers instead of a dielectric, but arcing to the trigger electrode again required precise alignments unless layers with high resistivity were used (thickness \( \sim 0.5 \) mm, resistivity \( \sim 10^6 \) \( \Omega \) cm).

The circuits in Figure 5(b) and 5(c) are equivalent to circuit (A) since only one pair of trigger electrodes changes its potential. No significant differences in the performance of the spark gaps was realized for these circuits as long as the right polarity was used. The performance of the gap with the circuit shown in Figure 5(d) was significantly worse with respect to delay and jitter.

The optimum position of the trigger electrodes was determined through measurements of the self-breakdown voltage shown in Fig. 6(a). In these experiments the pair of trigger electrodes was moved in the direction of the interelectrode spacing as shown in Fig. 6(b). The results clearly show the shielding of the edged main electrode resulting in an increase of the self-breakdown voltage of more than a factor of 2 compared to the gap without trigger electrodes. For optimum shielding no significant difference was observed for the two different types of trigger electrodes. The maximum self-breakdown voltage observed is nearly the uniform field breakdown value.

The following measurements on the trigger performance were obtained with the circuit in Fig. 5(a) and 5(d) and a positive charging voltage. All experiments are performed in atmospheric air. The rise time of the trigger pulse was of the order of 12 ns. Delay and jitter were determined by measuring the time between the voltage rise at the trigger electrode and at the main electrode. Figure 7 shows the delay depending on percent self-breakdown voltage (\( \% V_{SB} \)) for the two circuits. It should be pointed out that the maximum voltage of the trigger pulse always equals the charging voltage in the circuit used. So with a decreasing value of \( \% V_{SB} \) the maximum voltage of the trigger pulse automatically decreased.

As demonstrated in Fig. 7, a minimum delay time of 9 ns was achieved with circuit Fig. 5(a) for a self-breakdown voltage of 15 kV. Above 90\% \( V_{SB} \) self-breakdown the delay does not significantly change with \( \% V_{SB} \) as required for
FIG. 8. Jitter in pulse parameters. and maximum allowing the independent variation and it is likely that some gaps were operated at significantly lower values of self-breakdown voltage of each gap was difficult, however, on delay time and jitter indicate that this method may be suitable for a maximum hold-off voltage in the off-state spark gaps.

The experimental data on delay suggest that both mechanisms occur. For applied voltages near the static breakdown voltage, the delay is found to be approximately 10 ns. Considering the substantially reduced field in the region between the triggering electrode and electrode (2), electrons emitted from the cathode [electrode (2)] would require ~50 ns to traverse the gap. Thus, it seems difficult to explain delay times less than about 100 ns with the Townsend mechanism. At the opposite extreme, delays approaching 1 µs are observed for low applied voltages. Even considering the dielectric relaxation time required for a streamer to produce the high field enhancements needed in this regime, a streamer transit time exceeding 100 ns seems unlikely. Additional time is required, of course, to convert this streamer channel into an arc channel but this time should not be a strong function of the applied voltage, and considering the 10 ns delay observed at 95% $V_{SB}$, should not exceed several tens of nanoseconds at 50% $V_{SB}$. Thus the low voltage data suggest that a Townsend mechanism is at work. The two mechanisms, streamer and Townsend, are not incompatible, and it is likely that there is continuous transition from one to the other as the gap voltage is reduced.

V. PERSPECTIVES

The proposed trigger concept is well suited to combine field distortion with other trigger concepts to improve the switch performance. The important feature of this concept
here again is that the field enhancement occurs close to the surface of one main electrode and that this main electrode is partially shielded from the field in the hold-off state.

For trigatrons, it is well known that delay and jitter are drastically improved by overvolting the gap. Subsequently the combination of a trigatron trigger in the main electrode and a field enhancement generated by a field distortion in volume close to this trigatron electrode could provide for the same condition without the need to overvolt the total gap. The same considerations also hold for those laser triggered gaps where the laser spark is produced at or close to the surface of one main electrodes. The combination of the proposed field distortion concept with one of these trigger methods would therefore provide significantly improved performance in an undervolted main gap.
