In a recent Letter Tusche et al. [1] showed that a complete and coherent FeO layer forms on both interfaces of a Fe/MgO/Fe(001) magnetic tunnel junction (MTJ) when using oxygen-assisted growth. Their \textit{ab initio} model for these MTJs predicted tunneling magnetoresistance (TMR) of several thousand percent due to the contribution from interface resonances (IRs) perfectly matched at the two interfaces. In this Comment, we show that in practice the predicted giant TMR is unfeasible because the IRs are mismatched by structural disorder and/or by applied bias voltage resulting in a moderate TMR.

IRs are interfacial electronic states whose weak coupling to bulk states controls their intrinsic damping, $\gamma_0$. IRs produce large tunneling current in MTJs if they match identical resonances at the opposite interface [2]. Structural disorder leads to additional damping $\gamma$ and, if $\gamma \gg \gamma_0$, smears out the IRs over an area of the interface Brillouin zone (IBZ) proportional to $\gamma/\gamma_0$. This reduces the $k_{||}$-resolved transmission at resonance by a factor of $(\gamma/\gamma_0)^2$ and the total conductance by a factor of $\gamma/\gamma_0$ [3]. Since $\gamma_0$ may be very small compared to $\gamma$, the effect of disorder on the IR transmission may be significant.

We demonstrate the destructive effect of disorder on TMR in a symmetric Fe[FeO|MgO|FeO](001) MTJ with 5 monolayers of MgO. We perform first-principles calculations using the approach of Ref. [4] and a $800 \times 800$ mesh of $k_{||}$ points. The structural parameters are taken from Ref. [5]. Disorder is introduced by adding a small imaginary part to the energy, $\gamma$.

Figure 1 shows the resulting conductance and TMR as a function of $\gamma$. For weak disorder ($\gamma \ll \gamma_0 \sim 10^{-6}$ Ry) we find, in agreement with Ref. [1], a giant TMR of almost 7000%. This stems from the conductance for the parallel (P) configuration, $G_P = G_{||} + G_{||}$, being greater by two orders in magnitude than the conductance for the antiparallel (AP) configuration, $G_{AP} = 2G_{||}$. With increasing $\gamma$ the $G_P$ decreases dramatically, and for $\gamma \gg \gamma_0$ TMR drops by a factor of 50 to about 140%.

The giant TMR and its drop with disorder are the consequence of IRs formed at the two interfaces. Figure 2 shows the $k_{||}$- and spin-resolved transmission for $\gamma = 10^{-8}$ and $\gamma = 10^{-3}$ Ry [6]. The IRs are seen in the upper panels of Figs. 2(a) and 2(b) as extremely narrow lines. For $\gamma \ll \gamma_0$ they transmit with probability close to unity producing most of the tunneling current in the parallel configuration. With increasing $\gamma$ up to $10^{-3}$ Ry the maximum transmission value falls from 1 to about $10^{-4}$ and the overall transmission in the P configuration is reduced by two orders in magnitude. The transmission in the AP configuration is much less affected by disorder [Fig. 2(c)] due to a mismatch in the IRs resulting from dissimilar electronic structure at the two interfaces.

A similar effect is produced by a small applied bias voltage. Using a method of Ref. [4] we find that a bias voltage of 10 mV is sufficient to mismatch completely the IRs in the parallel configuration resulting in a drop of TMR by two orders in magnitude (from 7000% to 72%). Thus, both structural disorder and applied bias voltage destroy the resonant interface transmission making giant TMR in Fe[FeO|MgO|FeO](001) MTJs unfeasible.
