Abstract Mounting evidence suggests that helminth infections protect against autoimmune diseases. As helminths cause chronic IgE-mediated activation of basophils and mast cells we hypothesized that continuous activation of these cells could prevent diabetes onset in nonobese diabetic (NOD) mice in the absence of infection. Anti-FcεR1 activated basophils and mast cells and resulted in the release of IL-4 and histamine into the bloodstream. Anti-FcεR1-treated NOD mice showed a type 2 shift in insulin-specific antibody production and exhibited significant delays in diabetes onset. IL-4 responses played a partial role as the protective effect of anti-FcεR1 therapy was diminished in IL-4-deficient NOD mice. In contrast, histamine signaling was not required as anti-FcεR1-mediated protection was not reduced in mice treated with histamine receptor blockers. These results demonstrate that anti-FcεR1 therapy delays diabetes onset in NOD mice and suggest that chronic basophil and mast cell activation may represent a new avenue of therapy for Th1-associated autoimmune diseases.

1. Introduction

The prevalence of Type 1 diabetes and other autoimmune diseases has increased sharply over the past few decades [1–6]. While genetic factors play a role in susceptibility to Type 1 diabetes, it is probable that the dramatic worldwide increase in the prevalence of Type 1 diabetes is due to changes in environmental factors.

One environmental change that may be responsible for the recent increase in autoimmune diseases is the loss of chronic parasitic worm infections in developed countries. Multiple
studies have found that individuals with chronic parasitic worm infections have lower rates of autoimmune diseases than others living in the same environment (reviewed in [7]). Experimentally, parasitic worms have been shown to protect against Type 1 diabetes and other autoimmune diseases in several animal models [8–10], and in humans oral administration of porcine whipworm eggs results in protection against inflammatory bowel disease [11].

Until recently, most people had lifelong infections with parasitic worms. As helminths have been identified in neolithic and pre-Columbian mummies [12,13], it is likely that the human immune system evolved in the setting of chronic infection with these parasites [14]. Consequently, many scientists argue that the loss of parasitic worm infections is partially responsible for the increased prevalence of autoimmune and allergic diseases in developed countries—the notion being that now, in the absence of the immunomodulatory responses triggered by helminths, our immune systems have become hyperresponsive [9,14,15].

In this study, we sought to determine whether recapitulation of the IgE-mediated immune responses observed in chronic helminth infections can protect against Type 1 diabetes.
diabetes in the absence of actual infection. Unlike most bacterial or viral pathogens, helminth infections induce the production of specific IgE. This IgE binds to basophils and mast cells through FcεR1, the high affinity IgE receptor. Helminth-specific antigens can then activate basophils and mast cells by cross-linking IgE molecules and aggregating FcεR1s. As helminths are large organisms that release substantial amounts of antigen, and as these infections last for years, helminth infections likely induce a state of chronic basophil and mast cell activation. Indeed, recent time course studies in our lab demonstrate that both chronic basophil [16] and chronic mast cell activation (E. Mueller and E. Mitre, unpublished data) occur during infection of mice with the filarial nematode *Litomosoides sigmodontis*.

There are two mechanistic rationales for postulating that chronic activation of basophils and mast cells may protect against Th1-driven autoimmune disease. First, factors released by basophils and mast cells may have direct immunomodulatory properties that are protective against Th1-mediated autoimmune diseases. Basophils, for example, release large quantities of IL-4 when activated and have been shown to do so in response to parasite antigen in filaria-infected patients [17] as well as in animal models of helminth infection [16,18–20]. As destruction of beta-islet cells in Type 1 diabetes is driven by IFNγ release from Th1 cells, and as IL-4 counterregulates Th1 responses and has been shown to improve Th1-driven autoimmune diseases [21,22], it is possible that chronic basophil activation could protect against Type 1 diabetes by release of IL-4. Similarly, histamine, which is released from both basophils and mast cells, has been shown in vitro to suppress Th1 responses by signaling through the H2 receptor on lymphocytes [23]. Alternatively, chronic activation of basophils and mast cells could induce negative feedback pathways that tamp down ongoing autoimmune responses. Interestingly, there is substantial evidence that chronic immunotherapy, in which patients with IgE-mediated allergies are given weekly injections of allergen, augments immune regulatory networks such as the suppressive cytokine IL-10 and natural T-regulatory cells [24,25].

To test the hypothesis that chronic activation of basophils and mast cells can protect against a Th1-driven autoimmune disease, we studied the effects repeated anti-FcεR1 antibody injections have on the development of Type 1 diabetes in the NOD mouse model. Our studies demonstrate that anti-FcεR1 therapy activates basophils and mast cells, induces IL-4 and histamine release in vivo, and delays Type 1 diabetes onset in the NOD mouse. Studies using IL-4-deficient NOD mice and therapeutic histamine blockade reveal that IL-4, but not histamine signaling through H1 or H2 receptors, plays a partial role in the protective effects of anti-FcεR1 therapy.

2. Materials and methods

2.1. Mice

Female NOD and IL-4-deficient NOD.129P2(B6)-*Il4tm1Cgn*/DvsJ mice (The Jackson Laboratory) were maintained at the Uniformed Services University (USU) animal facility with free access to food and water. All experiments were performed under protocols approved by the USU Institutional Animal Care and Use Committee.

2.2. Assessment of diabetes

Glucose levels of mice were determined from blood taken by orbital bleeds every other week using a standard blood
glucose meter (Accu-Check Advantage, Roche Diagnostics GmbH). Mice with glucose levels greater than 230 mg/dl in two consecutive measurements were considered diabetic.

2.3. Treatment with anti-FcεR1

Beginning at 6-weeks of age mice were given weekly i.p. injections of 50 μg Armenian hamster anti-mouse FcεR1 (MAR-1, eBioscience) or control Armenian hamster IgG (Isotype Control, Functional Grade Purified, eBioscience) throughout the experiment. Subsets of animals were euthanized at 16 weeks of age, one day after the last anti-FcεR1 or IgG injection, to assess pancreas inflammation, splenic and pancreatic lymph node cytokine production, cell subtypes, as well as insulin-specific IgG1 and IgG2c levels.

Different shorter anti-FcεR1 treatment regimens were tested starting at 6-weeks of age. Those regimens included weekly i.p. injections of 50 μg anti-FcεR1 or control IgG for four weeks and i.p. injections of 25 and 50 μg anti-FcεR1 twice a week for four weeks.

2.4. Assessment of pancreas inflammation

At 16 weeks of age, pancreases were isolated and fixed in 10% formalin (Protocol, Fisher Scientific Company). Hematoxylin–eosin stained slices were assessed for inflammation by a pathologist blinded to the intervention group. Total numbers

Figure 3  Treatment with anti-FcεR1 delays the onset of diabetes. (A) Mean blood glucose levels and (B) percentages of NOD mice with diabetes during treatment with weekly injections of 50 μg anti-FcεR1 (n= 9) or IgG control antibody (n= 17). (C) Mean total numbers of pancreatic islets from anti-FcεR1 or isotype treated mice at 16 weeks of age (9–10 animals per group). Pancreatic islets were classified as non-infiltrated, periinsulitis, and intrainsulitis with less than or more than 50% infiltrated lymphocytes. (D) Blood glucose levels and (E) percentages of diabetic mice that received either weekly injections of 50 μg anti-FcεR1 for four weeks or injections of 25 or 50 μg anti-FcεR1 twice a week for four weeks (n =8 per group) or isotype controls (n =11). Error bars denote SEM. Statistical significance between groups was assessed by the Mann–Whitney test (*p<0.05). Shown are the combined results from 2 to 3 independent experiments.

(A) IFNγ, (B) IL-4, and (C) IL-5 cytokine production from spleen cells and (D) IFNγ and (E) IL-5 cytokine production from pancreatic lymph node cells in response to anti-CD3/anti-CD28. (F) Frequency of splenic CD4+IFNγ+ and (G) CD8+IFNγ+, as well as (H) CD4+IL-4+ and (I) CD4+IL-17+ T cells in response to anti-CD3/anti-CD28. (J) Plasma levels of insulin-specific IgG1 and (K) IgG2c. Statistical significance between groups was assessed by the Mann–Whitney test. Shown are the results from two independent experiments with a total of 9–10 animals per group.
of islets of three longitudinal sections 400 μm apart of each pancreas were assessed. The severity of insulitis was scored as non-infiltrated, periinsulitis (lymphocytes at the periphery of islets), or intrainsulitis (lymphocyte infiltration into the interior of the islets lesser or greater than 50%).

2.5. Spleen and pancreatic lymph node cell culture

At 16 weeks of age, animals that were treated for 10 weeks with either anti-FcεR1 or control IgG were euthanized and spleen and pancreatic lymph nodes were isolated. Spleen and pancreatic lymph node cells were prepared and cultured as previously reported [8]. In brief, single cell suspensions were obtained, red blood lysis was performed for spleen cells (ACK Lysing Buffer, Quality Biological, Inc.), and cells were plated at a concentration of 2×10⁶ cells/ml in enriched media (Iscove’s Dulbecco modified medium (Mediatech) including 10% fetal calf serum (Valley Biomedical), 1% insulin–transferrin–selenium medium (Invitrogen Inc.) and 80 μg/ml gentamicin (Quality Biological, Inc.)), stimulated with 5 μg/ml anti-CD3 and 2 μg/ml anti-CD28 (eBioscience), and cultured at 37 °C, 5% CO₂.

2.6. Flow cytometric analysis of regulatory cell types and intracellular cytokine production by T cells

Spleen and pancreatic lymph node cells were cultured as described above and prepared for flow analysis as previously reported [8]. In brief, after two hours of incubation, BD GolgiStop was added (BD Biosciences) and cells were incubated for an additional four hours. Collected cells were fixed and permeabilized (eBioscience) overnight. For analysis cells were washed once with phosphate-buffered saline (PBS)/1%BSA (bovine serum albumin, Sigma), followed by a blocking step with PBS/1%BSA. Cells were washed with 1× permeabilization buffer (eBioscience) and stained for five- or four-color-flow
using CD4 PerCP, IL-4 APC (BD Biosciences), CD8a Pacific Blue, gamma interferon (IFN-γ) FITC, and IL-17 PE (eBioscience) or CD4 PerCP (BD Biosciences), FoxP3 FITC, CD25 APC-Alexa Fluor 750, and IL-10 PE (eBioscience). For identification of regulatory CD8 T-cells and regulatory B cells, fixed, cryopreserved (PBS/10% DMSO) spleen cells were washed once, blocked with CD16/CD32 (BD Biosciences) and stained with CD4 Qdot 605 (Invitrogen), CD8 PE Cy5, FoxP3 FITC, (all eBioscience) or B220 PerCP, CD1d FITC, CD5 APC (all BD Biosciences), and IL-10 PE (eBioscience). Flow cytometry was performed using a BD LSRII system and subsequently analyzed with FACSDiva 6.1 software (BD Biosciences).

2.7. Measurement of cytokines and antibodies by ELISA

Cytokine enzyme-linked immunosorbent assays (ELISAs) were performed from spleen and pancreatic lymph node cell cultures. Culture supernatants from cells that were cultured using CD4 PerCP, IL-4 APC (BD Biosciences), CD8a Pacific Blue, gamma interferon (IFN-γ) FITC, and IL-17 PE (eBioscience) or CD4 PerCP (BD Biosciences), FoxP3 FITC, CD25 APC-Alexa Fluor 750, and IL-10 PE (eBioscience). For identification of regulatory CD8 T-cells and regulatory B cells, fixed, cryopreserved (PBS/10% DMSO) spleen cells were washed once, blocked with CD16/CD32 (BD Biosciences) and stained with CD4 Qdot 605 (Invitrogen), CD8 PE Cy5, FoxP3 FITC, (all eBioscience) or B220 PerCP, CD1d FITC, CD5 APC (all BD Biosciences), and IL-10 PE (eBioscience). Flow cytometry was performed using a BD LSRII system and subsequently analyzed with FACSDiva 6.1 software (BD Biosciences).

2.7. Measurement of cytokines and antibodies by ELISA

Cytokine enzyme-linked immunosorbent assays (ELISAs) were performed from spleen and pancreatic lymph node cell cultures. Culture supernatants from cells that were cultured

Figure 6  Histamine receptor blockage does not decrease anti-FcεR1 mediated delay of diabetes onset. (A) Stomach pH from animals that were treated for 2 weeks with the histamine receptor blockers cimetidine and fexofenadine (5 animals per group). (B) Representative pictures of mice that were injected i.v. with toluidine blue following intradermal challenge with anti-FcεR1 (left ear) and IgG control (right ear). The bottom mouse was treated with fexofenadine, a histamine receptor 1 blocker, whereas the top mouse is an untreated control. (C) Blood glucose levels and (D) percentages of NOD mice with diabetes in the setting of continuous administration of histamine receptor blockers (anti-HR1/2) and treatment with weekly injections of 50 μg anti-FcεR1 or IgG control antibody. Shown are the results from two independent experiments with a total of 10 mice per group. Error bars denote SEM. Statistical significance between groups was assessed by the Mann–Whitney test (*<0.05).

Figure 7  Deficiency of IL-4 reduces anti-FcεR1 mediated protective effect. (A) Blood glucose levels and (B) percentages of mice with diabetes in IL-4 deficient NOD mice that were injected weekly with 50 μg anti-FcεR1 (n = 11) or an IgG control antibody (n = 15). Error bars denote SEM. Statistical significance between groups was assessed by the Mann–Whitney test. Shown are the results from four independent experiments.
as described above and stimulated with anti-CD3 and anti-CD28 were collected after 72 h of incubation. IFN-γ, IL-4, IL-5, and IL-10 were quantified according to the manufacturer's instructions (BD Biosciences).

Plasma derived insulin-specific IgG1 and IgG2c were analyzed by sandwich ELISA as previously described [8]. All samples were analyzed as duplicates at the same time on the same plate to allow accurate comparison between groups by OD.

2.8. Flow cytometric analysis of basophils and mast cells

Frequency of basophils in the peripheral blood and peritoneal mast cells was measured by flow cytometry one day after a single injection of 50 μg anti-FcεRI control IgG in 8-week old female NOD mice.

Basophil flow was performed as previously described [26]. In brief, 100 μl of blood obtained by orbital bleeding was diluted with 100 μl of RPMI media (RPMI-1640, Mediatech), red blood cells were lysed and cells were fixed (whole blood lysing reagent kit, Beckman Coulter, Inc.). After two washing steps with 1× PBS, cells were blocked overnight with PBS/1% BSA. Cells were washed and stained with IgE FITC (BD Biosciences), CD4 PerCP (BD Biosciences) and B220 PerCP (BD Biosciences). During flow cytometric analysis, basophils were identified as CD4−/B220−/IgE+ cells.

Mast cells were obtained by a peritoneal wash with 1× HBSS (Gibco) and fixed after red blood cell lysis (whole blood lysing reagent kit, Beckman Coulter). Cells were washed once and blocked overnight in PBS/1% BSA. 1 × 106 peritoneal cells were stained for flow with IgE FITC (BD Biosciences) and cKit APC (BD Biosciences). During flow cytometric analysis, mast cells were identified as IgE+/cKit+ cells.

2.9. Detection of histamine from in vitro stimulated purified mast cells

For in vitro activation of mast cells, peritoneal mast cells were purified using a 70% percoll gradient. 2000 mast cells were cultured in 250 μl histamine release buffer (Immunotech S.A.S.) and stimulated with isotype (10 μg/ml) or anti-FcεRI (0.4, 1.6, 6.25, 25, 100 μg/ml) for 30 min. Cells were acylated and histamine ELISA performed according to the manufacturer's instructions (Immunotech S.A.S.).

2.10. Intracellular IL-4 detection of in vitro stimulated basophils

For intracellular IL-4 detection of basophils, 100 μl of peripheral blood from NOD mice cultured with GolgiStop (BD Bioscience) and either media, 10 μg/ml isotype control, 10 or 25 μg/ml anti-FcεRI (MAR-1) for a total of 6 h at 37 °C. Following red blood lysis and fixation (performed as mentioned above) cells were stained in a two step procedure for flow. Cells were stained for the surface markers IgE FITC, CD4 PerCP, and B220, followed by permeabilization (permeabilization buffer, BD Bioscience) and staining with IL-4 APC (BD Bioscience).

As basophils are the only circulating cells in mice that express FcεRI, IL-4 release from whole blood was measured after in vitro stimulation of 100 μl of peripheral blood from NOD mice cultured with 10 μg/ml anti-FcεRI antibody, 10 μg/ml IgG isotype control, or media for 6 h at 37 °C. Plasma was obtained by centrifugation and stored at −20 °C until the IL-4 ELISA was performed as per the manufacturer's instructions (eBioscience).

2.11. In vivo cytokine capture assay to detect IL-4 release after anti-FcεRI injection

10 μg biotinylated IL-4 antibody (BD Bioscience) was injected i.p. into 11-week old NOD mice. The following day mice were injected i.p. with 50 μg anti-FcεRI or control IgG and one day later blood was collected by orbital bleed. Concentration of IL-4 was measured by ELISA according to the manufacturer's instructions (BD Biosciences).

2.12. Detection of in vivo histamine release after injection of anti-FcεRI

Mice were i.p. injected with a single dose of 50 μg anti-FcεRI or control IgG. After 30 min, blood was collected by orbital bleed. 100 μl of blood was immediately acylated and histamine ELISA was performed according to the manufacturer's instructions (Immunotech S.A.S.).

2.13. Treatment with histamine receptor blockers

Starting at 6-weeks of age, 2.5 mg/ml cimetidine (Sigma), an H2-receptor blocker, and 0.25 mg/ml fexofenadine HCl (TEVA Pharmaceuticals USA), an H1-receptor blocker, were added to the drinking water of NOD mice. The treated drinking water was freshly prepared every other day throughout the experiment until 25 weeks of age.

Efficacy of H2-receptor blockage was tested by measuring the stomach pH 2 days after changing the drinking water in mice that had been receiving fexofenadine and cimetidine treatments for 2 weeks. Mice were euthanized and the stomach pH was measured using pH strips (Micro Essential Laboratory). In addition, blockage of the histamine-receptors was confirmed in vivo by injecting 10 μg anti-FcεRI intradermally into one ear and 10 μg control IgG in the other, followed by i.v. injection of 200 μl toluidine blue (Sigma, 0.5% in PBS) 3 min later. The ears were dissected 10 min later and vascular permeability was measured at 620 nm by the optical density (OD) of the blue dye extracted from the ears after o.n. incubation at 63 °C in Formamide (Sigma).

2.14. Statistics

Statistical analyses were performed with GraphPad Prism software (GraphPad Software). Differences between paired groups for in vitro studies were analyzed using one-tailed paired T-test and differences between two unpaired groups for in vivo studies were tested for significance with the Mann–Whitney U-test. P-values < 0.05 were considered significant. All experiments were performed at least twice.
3. Results

3.1. Anti-FcεR1 antibody activates basophils and mast cells of NOD mice

To evaluate the effects anti-FcεR1 antibody has on mast cells in vitro, histamine release from mast cells purified from the peritoneal cavity of NOD mice was assessed in response to in vitro incubation with various concentrations of anti-FcεR1. Density gradient centrifugation of peritoneal cells resulted in high level enrichment of mast cells (>70% purity for all samples, Fig. 1A). While incubation of enriched mast cells with media or isotype antibody resulted in no demonstrable histamine release above incubation with media alone, incubation with increasing concentrations of anti-FcεR1 antibody resulted in a classical mast cell activation curve (Fig. 1B).

To determine whether anti-FcεR1 antibody also activates basophils in vitro, whole blood samples from NOD mice were assessed for basophil IL-4 production by intracellular flow cytometry. Basophils were identified by flow cytometry as CD4−B220−IgE+ cells (Fig. 1C) as this staining strategy has been shown to be specific for basophils [26]. Whereas an average of 18% of basophils stained positively for IL-4 at baseline, on average 65% were IL-4+ after incubation with anti-FcεR1 (p<0.0001, Fig. 1D). To confirm that anti-FcεR1 induces IL-4 release from basophils, IL-4 was measured by ELISA in the supernatants of whole blood samples incubated with media or anti-FcεR1. As seen in Fig. 1E, anti-FcεR1 caused significant release of IL-4 from whole blood (unstimulated mean IL-4 concentration 32 pg/ml vs. mean 77 pg/ml after anti-FcεR1 stimulation, p=0.03). As basophils are the only circulating cells in mice that express FcεR1, this assay confirms that anti-FcεR1 antibody induces IL-4 release from basophils.

3.2. Anti-FcεR1 injections deplete basophils and induce massive histamine and IL-4 release in vivo

As both basophils and mast cells express the FcεR1 on their surface, we tested whether treatment with anti-FcεR1 antibody depletes either peripheral basophils or peritoneal mast cells by injecting NOD mice with 50 μg of anti-FcεR1 and measuring blood basophil and peritoneal mast cell frequencies by flow cytometry. The frequency of blood cells that were basophils was significantly reduced one day after treatment with anti-FcεR1 antibody compared to control animals (median 0.11%, range 0.05–0.19% vs. 0.40%, 0.19–0.63%, Fig. 2A) whereas the frequency of peritoneal mast cells was unchanged (median 1.8%, range 0.2–2.5% vs. 2.1%, 0.1–3.2%, Fig. 2B). This finding is consistent with that of other research groups who have used anti-FcεR1 antibody to deplete mice of basophils [20,27].

Because aggregation of surface FcεR1 activates basophils and mast cells, and since our in vitro studies demonstrated that anti-FcεR1 antibody induces basophils and mast cells to release IL-4 and histamine, we tested whether injection of anti-FcεR1 antibody increases blood levels of IL-4 and histamine. As seen in Fig. 2C, mice that were injected the previous day with anti-FcεR1 had significantly higher frequencies of circulating IL-4, as measured by in vivo cytokine capture assay, compared to isotype antibody treated controls (p=0.0015, median 863 pg/ml, range 0–1173 pg/ml vs. 10 pg/ml, range 0–34 pg/ml). Similarly, histamine, which was measured in peripheral blood obtained 30 min after antibody injection due to its very short half-life, was substantially higher in anti-FcεR1-treated mice than in controls. Mice that received anti-FcεR1 had a median blood histamine concentration of 28,800 nmol (range 7745–137,700 nmol) as compared to only 248 nmol (range 81–441 nmol, p<0.0001, Fig. 2D). As basophils and mast cells are the only cells that contain pre-formed histamine, these results demonstrate that anti-FcεR1 antibody injection activates basophils and mast cells in vivo.

3.3. Anti-FcεR1 treatment delays diabetes onset in NOD mice

To test the hypothesis that chronic activation of basophils and mast cells protects against autoimmune diseases, development of Type 1 diabetes was monitored in NOD mice that were given weekly anti-FcεR1 antibody injections from 6 weeks of age.

Repeated injections with anti-FcεR1 significantly reduced blood glucose concentrations in NOD mice at 20 and 24–28 weeks of age compared to control animals (Fig. 3A) and delayed the onset of diabetes (onset of diabetes in 50% of the animals: IgG group: 20 weeks of age, anti-FcεR1: 30 weeks of age, Fig. 3B). Histological analysis of the pancreas revealed that anti-FcεR1-treated mice had an increased total number of β-islet cells and less lymphocyte infiltration of the pancreatic islets compared to IgG treated mice at 16 weeks of age, although these differences were not statistically significant (Fig. 3C).

Shorter anti-FcεR1 antibody treatment periods from 6 to 9 weeks of age did not provide a similar protective effect. Neither 4 weekly injections with 50 μg of anti-FcεR1 antibody, nor 4 weeks of injections with 25 or 50 μg twice a week decreased blood glucose levels or the frequency of diabetic NOD mice compared to isotype antibody-treated controls (Figs. 3D,E).

3.4. Anti-FcεR1 treatment induces a Th2 shift in antibody, but not cytokine production

The effect 10 weeks of anti-FcεR1 treatment has on cellular cytokine production was evaluated from spleen and pancreatic lymph node cells of 16 week old NOD mice after stimulation with anti-CD3/anti-CD28. IFNγ and IL-4 levels were similar between isotype antibody-injected controls and anti-FcεR1-treated animals (Figs. 4A,B), whereas the concentration of IL-5 was significantly increased in anti-FcεR1-treated mice (Fig. 4C). Pancreatic lymph node cells from anti-FcεR1-injected mice produced more IL-5 and IFNγ, in response to anti-CD3/anti-CD28 compared to controls, although these differences did not reach statistical significance (Figs. 4D,E).

Frequencies of splenic CD4+IFNγ+ T cells and CD8+IFNγ+ T-cells (Figs. 4F,G) as well as CD4+IL-4+ T-cells (Fig. 4H) after in vitro stimulation with anti-CD3/anti-CD28 were not significantly affected by anti-FcεR1 treatment. Frequencies of splenic anti-CD3/anti-CD28 stimulated CD4+IL-17+ T-cells
were increased in anti-FcεR1-treated animals compared to controls, though this difference did not reach statistical significance (p=0.079, Fig. 4I).

As antigen-specific cellular immune responses are difficult to detect in NOD mice, we tested whether repeated anti-FcεR1 antibody injections induce either insulin-specific Th1 (IgG2c) or Th2 (IgG1) associated antibody subsets. Mice that were treated for 10 weeks with anti-FcεR1 antibodies had significantly increased levels of insulin-specific IgG1 compared to isotype antibody-injected controls whereas levels of insulin-specific IgG2c were unchanged (Figs. 4J,K).

3.5. Anti-FcεR1 treatment induces a marginal increase in regulatory responses

Frequencies of regulatory T and B cells and the production of the immunoregulatory cytokine IL-10 were measured from spleen and pancreatic lymph node cells in response to anti-CD3/anti-CD28 after 10 weeks of anti-FcεR1 antibody treatment to assess the development of a regulatory immune response.

While repeated anti-FcεR1 antibody treatment did not substantially alter the percentage of CD4+ T-cells that were CD25+FoxP3+ in the spleen (mean 12.5% in isotype treated mice vs. 13.3% in anti-FcεR1-treated, Fig. 5A), mean percentages of CD4+CD25+FoxP3+ regulatory T cells in the pancreatic lymph nodes did increase substantially (3% in isotype-treated vs. 5.2% in anti-FcεR1-treated, Fig. 5B) though this difference did not reach statistical significance (p=0.17).

Similarly, percentages of CD8+ spleen cells that were positive for FoxP3+ (Fig. 5C), splenic B-cells that produced IL-10 (Fig. 5D), and splenic B-cells that expressed a regulatory phenotype (B220+CD1d+CD5+, Fig. 5E) were all increased after anti-FcεR1-treatment, though none reached statistical significance.

Repeated anti-FcεR1 antibody injections also slightly increased splenic (p=0.18, Fig. 5F) and pancreatic lymph node cell (p=0.44, Fig. 5G) IL-10 production in response to anti-CD3/anti-CD28, though again the increases were not statistically significant.

3.6. Histamine signaling through H1 and H2 receptors is not necessary for anti-FcεR1 induced delay of Type 1 diabetes

As injection with anti-FcεR1 resulted in the release of increased amounts of histamine and as histamine can have immunomodulatory properties, we tested whether blockade of H1 and H2 histamine receptors would prevent anti-FcεR1-mediated delay of diabetes onset in NOD mice.

Cimetidine (an H2 receptor blocker) and fexofenadine (an H1 receptor blocker) were administered by addition to the drinking water of NOD mice from 6 weeks of age to study endpoint at 25 weeks of age at concentrations used by prior investigators [28,29].

Efficacy of H2-receptor blockade was confirmed by a significant increase in the stomach pH of treated animals from 6 weeks of age to study endpoint at 25 weeks of age. This result was unexpected, as basophils and mast cells both release histamine and IL-4 in response to FcεR1-mediated signaling. We suspect that the bulk of the IL-4 release was due to basophil activation, since basophils are the only cells known to store large quantities of pre-formed IL-4 [30], are major contributors of IL-4 in helminth infections and allergic diseases [17,18,31], and have been demonstrated to release more IL-4 on a per cell basis than other cell types [32,33]. To our knowledge this is the first demonstration that chronic
activation of basophils and mast cells is associated with protection against autoimmunity.

Although continuous treatment with anti-FcεR1 antibody did not result in a clear Th2 shift in cytokine production, as measured from spleen and pancreatic lymph node cells, increases in insulin-specific IgG1 revealed a type 2 immune shift in antibody production. Increased serum levels of IL-4 following anti-FcεR1 antibody treatment suggest that this type 2 immune shift in antibody responses may have been driven by IL-4 released from innate cells activated by antibody rather than T-cells. This type 2 immune shift in insulin-specific antibody isotypes is similar to that observed when NOD mice are infected with the filarial nematode *Litomosoides sigmodontis* [8], an intervention that also results in protection against diabetes.

While histamine signaling through H1 and H2 receptors does not appear necessary for protection, as treatment with H1 and H2 receptor blockers did not attenuate the protective effects of anti-FcεR1 injections, results obtained with IL-4 deficient NOD mice demonstrate that IL-4 is partly responsible for the therapeutic benefit. The finding that IL-4 protects against autoimmune disease is consistent with prior studies. In NOD mice systemic administration of IL-4 [34,35], expression of IL-4 by pancreatic β-islet cells [36], and transfer of IL-4 expressing DCs [37,38] have been shown to prevent the onset of autoimmune diabetes. An important role for IL-4 in the control of Th1-driven autoimmune diseases is further suggested by studies that used helminths to prevent autoimmunity. Helminth or helminth antigen induced protection against autoimmune diabetes is associated with the induction of Th2 immune responses [8] and studies in experimental autoimmune encephalitis and trinitrobenzene sulfonic acid (TNBS) induced colitis showed that *Schistosoma* egg administration failed to protect against autoimmunity in mice deficient in STAT6 or depleted of IL-4 [39].

Besides counterbalancing Th1 immune responses, FcεR1-induced IL-4 may protect against Th1 driven autoimmune responses by driving the differentiation of classically activated (Th1 associated) macrophages into an alternative activated phenotype (AAMØ). AAMØ are anti-inflammatory and are known to be more prevalent during helminth infections [40]. Future studies will investigate whether FcεR1-treatment induces AAMØ and whether this cell population contributes to the protective effect.

The novelty of this study is that we were able to induce IL-4 release by systemically activating basophils and mast cells with an antibody that directly cross-links FcεR1s. An approach that is based on antibody injections to trigger IL-4 release might be easier to transfer to the bedside compared to therapies that consist of injection with cytokines.

Additionally, given that the protective effects of anti-FcεR1 therapy were only partially reduced in IL-4-deficient NOD mice, it is likely that IL-4 independent mechanisms may also play a role in anti-FcεR1 therapy. These may be directly related to activation of basophils and/or mast cells, or they may be due to induction of negative feedback pathways induced by chronic activation of these cells. Determining the protective mechanisms of repeated anti-FcεR1 injections that are IL-4 independent will be a focus of studies in the future.

One IL-4-independent mechanism may be the induction of IL-13 release by anti-FcεR1 injections as IL-13 has been shown to prevent diabetes onset in NOD mice [41]. Both basophils and mast cells can produce IL-13 after cross linking of FcεR1. Because IL-13 signals through IL-4Rα it is possible that anti-FcεR1-induced IL-13 assumed some of the functions of IL-4 in IL-4 deficient NOD mice and contributed to anti-FcεR1 mediated protection. Evaluating whether IL-13 plays a role in anti-FcεR1 mediated protection against autoimmunity will be the subject of future studies.

In contrast, the observed non-significant increase of Th17 cells during anti-FcεR1 therapy is very unlikely to be a mechanism by which anti-FcεR1 injections protect against Type 1 diabetes since Th17 responses are thought to have a role in the induction of Type 1 diabetes, possibly by conversion of Th17 to Th1 cells that can cause diabetes onset [42–45].

Another IL-4-independent mechanism that may be important is the induction of immunoregulatory networks. By repeatedly activating basophils and mast cells, we replicated the immunological phenotype observed in chronic helminth infections and in allergen immunotherapy. In helminth infections, basophils and mast cells are continuously being activated by parasite antigens through parasite-specific IgE on the surface of these cells [16]. In immunotherapy, patients with allergen-specific IgE are repeatedly given injections of allergen to which they have specific IgE, essentially inducing a chronic state of low level basophil and mast cell activation. While the mechanisms by which chronic helminth infections and allergen immunotherapy modulate the immune system are not completely understood, a number of studies show that both augment key regulators of peripheral tolerance such as IL-10 and T-regulatory cells. Indeed, helminth infections shown to protect against autoimmune diseases in animal models have been repeatedly associated with increases of IL-10 and T-regulatory cells [8,46,47].

In our study, while not statistically significant, levels of IL-10 production from splenocytes, frequencies of IL-10 producing B cells, and frequencies of regulatory CD4+FoxP3+ T-cells, CD8+FoxP3+ T-cells, and CD1d+CD5+ B-cells were all higher in mice receiving anti-FcεR1 antibody injections. As one of the hallmarks of autoimmune diseases is the loss of peripheral tolerance [48], it will be important for future studies to more fully evaluate whether anti-FcεR1 therapy functions by augmenting peripheral tolerance. In a similar vein, it would be interesting to evaluate whether allergen immunotherapy in allergic patients has had beneficial effects on patients with concurrent autoimmune diseases.

Future studies will also attempt to further define exactly which cells are involved in anti-FcεR1-mediated protection. In particular, it will be important to determine whether basophils and/or mast cells are necessary for the protective effects of anti-FcεR1 therapy. We have shown that anti-FcεR1 therapy activates these cells, but have not yet demonstrated that these cells are essential. As there are currently no basophil-deficient nor mast-cell deficient mice on a NOD background, it will be necessary to develop techniques of depleting basophils and mast cells without concurrently activating them. Additionally, it has recently been shown that antigen-presenting DCs can express FcεR1 in the setting of Th2 inflammation and be depleted by anti-FcεR1 treatment [49]. While it is unlikely these cells play a role in the Th1-mediated pathology of Type 1 diabetes, future studies will also evaluate whether FcεR1+ DCs play a role in FcεR1-mediated protection against Type 1 diabetes.

Clinically, it is important to ask whether induction of chronic basophil and mast cell activation could actually be
used to protect against autoimmune diseases. While at first blush such an approach sounds preposterous given the obvious risk of anaphylaxis, we believe that chronic basophil and mast cell activation could be a safe and feasible therapy. We propose that the key to safety would be to start treatment with small amounts of anti-FcεR1 antibody, or another basophil/mast cell activating agent, followed by a gradual increase in treatment dosage. Repeated administration of gradual increasing amounts of anti-FcεR1 did not cause anaphylaxis in the mice we studied, and such an approach would be similar to allergen immunotherapy, in which the dose of allergen given is gradually increased over time. Allergen immunotherapy induces repeated basophil and mast cell activation and is routinely conducted in the outpatient arena for diseases as benign as allergic rhinitis.

Importantly, unlike conventional therapies for autoimmune diseases which predominantly work by incapacitating specific arms of the immune system, a therapeutic approach based on the induction of chronic basophil and mast cell activation has the potential to induce a therapeutic effect without irreversibly inhibiting any pathways of the immune system.

In conclusion, this study demonstrates that repeated administration of anti-FcεR1 antibodies results in activation of basophils and mast cells and protection against Type 1 diabetes in NOD mice by a mechanism that is partially dependent on IL-4. While IL-4 has been previously shown to protect against Th1-driven autoimmune diseases, the utilization of repeated antibody injections to induce IL-4 release represents a novel approach for the treatment of autoimmune diseases. Given the feasibility of developing antibodies for use in humans, such an approach has the potential to be translated into a novel clinical therapy for Th1-driven autoimmune diseases. In addition to evaluating the safety and feasibility of this approach as a therapy for humans with autoimmunity diseases, future studies will also focus on obtaining a better understanding of how helminth infections protect against autoimmune diseases to enable development of other novel therapeutic strategies.

Conflict of interest statement

Drs. Mitre and Hübner are co-inventors on U.S. Provisional Patent Application No. 61/382,541 "Chronic basophil activation as a therapy for Th1-driven autoimmune diseases".

Acknowledgments

We thank Dr. J. Thomas Stocker from the Dept. of Pathology at USU for his help to assess inflammation in the pancreas and Dr. Kristin Tarbell from NIH/NIDDK for helpful discussions on working with the NOD model of diabetes. This work was supported by grants 1DP2DK083131 from NIH/NIDDK and R073MX from the Uniformed Services University of the Health Sciences.
