(Received 15 February 2002; accepted 23 April 2002)

A hybrid thermodynamic and density-functional theory for heterogeneous nucleation on mesoscopic wettable particles is developed. The nonlocal density-functional theory (DFT) is on basis of the weighted-density approximation (WDA) of Tarazona. The model system consists of a Lennard-Jones (LJ) fluid and a 9–3 LJ wall for the solid particle. Effects of the droplet curvature and compressibility are accounted for in the theory. A by-product of this work is the calculation of the Tolman length using the WDA-DFT (Appendix A). Important characteristics of the heterogeneous nucleation, including the chemical potential of the liquid condensate, the free energy of droplet formation, and the barrier height to nucleation, are obtained. © 2002 American Institute of Physics. [DOI: 10.1063/1.1485733]

I. INTRODUCTION

Heterogeneous nucleation is the most common mechanism in initiating a first-order phase transition. For example, from a metastable supersaturated vapor to the bulk liquid, the nucleation process often proceeds with the formation of a liquid-like film on the surface of foreign particles. Many kinds of particles can act as heterogeneous-nucleation centers. These include ions, droplets of acid, solutable or unsoluble sols, and dust particles. It is known that thermodynamic properties of the liquid film formed on the surface of a particle depend strongly on the nature of the surface force. A general feature for heterogeneous nucleation is the existence of a threshold supersaturation beyond which the so-called barrierless nucleation can take place. In comparison, the homogeneous nucleation which occurs only in an impurity-free environment, is much less common in nature. In fact, the homogeneous nucleation always requires a higher value of supersaturation than that for heterogeneous nucleation. This was first recognized by Volmer in 1939. Since then, studies of heterogeneous nucleation have received considerable attention. Recent reviews on this subject can be found in Refs. 2–4.

In this paper we consider the heterogeneous nucleation on mesoscopic spherical particles. Droplet formation on the particles can be developed in two ways, depending on the wettability of the liquid on the surface of the particle. The first possible way is the formation of a liquid film on the entire surface of the particle (complete wetting). The film then grows into a large liquid droplet with the foreign particle at the center. The second way is via forming microlenses of liquid on the surface of the particle with a nonzero contact angle. These separate microlenses then grow in size, collapse into a thick film which covers the entire surface of the particle, and then develop into a large liquid droplet. In this study, we consider only the first possibility. A sufficient condition for this possibility is that the liquid condensate will wet the surface of the particle completely as the radius approaches infinity (or the coefficient of spreading of the condensate is positive in the planar limit).

As mentioned above, the thermodynamic properties of the liquid condensate on the mesoscopic particles strongly depend on the nature of the surface force. In the classical theory of heterogeneous nucleation, several empirical parameters were introduced to describe the surface forces. These parameters are generally taken either from experiments or from other microscopic theories or molecular simulations, for example, the molecular theory of capillarity and the density-functional theory, or molecular dynamics and Monte Carlo simulations. Molecular simulations have been used extensively to explore various wetting phenomena on a planar solid surface and have yielded important results such as the dependence of wetting temperature and the surface critical temperature on the surface force, as well as the density profiles of the liquid film near the solid surface. Density-functional theory (DFT) has also been employed by many workers to study behavior of a fluid near a solid surface. In most studies, the so-called weighted density approximation (WDA) developed by Tarazona is adopted. The WDA has been shown to be very accurate for describing highly nonuniform solid–liquid interfacial systems. Both DFT and molecular simulations have their own advantages and shortcomings. In molecular simulations, the number of molecules in the simulation cell is finite (typically, a few thousand), whereas a typical mesoscopic size of droplet possesses at least millions of molecules. Although DFT is free from such size limitation, it requires certain approximation in the correlation function and free-energy functional, which renders the calculation less accurate. Here, we use the DFT because we are interested in the formation of liquid droplets on mesoscopic particles. Moreover, the DFT has been used in many previous studies of homogeneous nucleation.

As discussed above, a planar surface can be considered as the limiting case for a mesoscopic particle when its diameter approaches infinity. For the planar surface, the complete wetting may occur when the nucleating vapor is undersatu-
It is well known that the local density approximation (LDA) was the basis for all these studies, namely, the second possible way of heterogeneous nucleation described above. In that case, the line tension of the three-phase interface on the solid surface must be considered. The solid surface can be either planar or curved. DFT with a local gradient expansion was the basis for all these studies. It is well known that the local density approximation (LDA) cannot qualitatively describe the structure of the density profile near the solid surface. Thus, we will use the nonlocal WDA-DFT. We will present a hybrid approach by combining the DFT with a classical nucleation theory. The latter yields general relations among thermodynamical and kinetic properties of the system, while the DFT provides important properties of the liquid droplet, such as the dependence of the chemical potential of the liquid droplet on the droplet size. Outcomes of the hybrid theory include the threshold value of the chemical potential (or the threshold value of the supersaturation) for barrierless nucleation, the height of the activation barrier to nucleation, the half-width of the barrier, as well as the position of the minimum and maximum on the curve of free energy of droplet formation versus the droplet size.

This paper is organized as follows: In Sec. II several main aspects of the thermodynamics of heterogeneous nucleation are discussed. In Sec. III the DFT with the WDA of Tarazona is briefly discussed and the application to a wetting liquid film on the planar solid surface is reviewed. Characteristics of the chemical potential of the liquid condensate are described and chemical potential of the liquid condensate as a function of molecular number in the liquid film is given in Sec. IV. Key properties of heterogeneous nucleation, such as the free energy of droplet formation and the barrier height to nucleation, are presented in Sec. V. Final conclusions are given in Sec. VI. In Appendix A, we present generalized Blokhuis-Bedeaux formulas for the surface tension and the Tolman length by accounting for the effect of the nonlocal WDA.

II. THERMODYNAMICS OF HETEROGENEOUS NUCLEATION

Several main thermodynamic equations such as the Laplace equation and Gibbs–Duhem equation form the basis for the description of any droplet-like object in the classical nucleation theory. In this section we formulate generalized version of these equations for the description of heterogeneous nucleation on mesoscopic wettable particles.

The system considered here is an open system which consists of a mesoscopic wettable solid particle and a metastable vapor at a fixed temperature and volume. Upon condensation, a liquid film with a uniform thickness will form on the surface of particle (complete wetting). Assuming the system has spherical symmetry, the density profile of the system is given by \( \rho(r) \), where \( r \) is the distance from the center of the solid particle. Hereafter, we refer the metastable vapor as phase 1, the liquid film as phase 2, and the solid particle as phase 3. In describing the thermodynamics of this nonuniform system, we use the Gibbs method of dividing surfaces to replace \( \rho(r) \) by a step-like density profile, similar to the sharp-kink model introduced by Getta and Dietrich. This new density profile consists of the solid particle with density \( \rho_3 \), the liquid film with density \( \rho_2 \) which equals the bulk density of liquid at the current supersaturation, and the vapor with density of \( \rho_1 \). The solid particle has a radius \( R_n \). We use \( R_n \) to represent its physical radius and \( R_n \) for the radius of the solid–liquid dividing surface. \( R_n \) may differ from \( R_n \) by few molecular diameter, depending on the thickness of the solid–liquid interface. Following Ref. 18, we set zero density between \( R_n \) and \( R_n \). The radius of the liquid–vapor dividing surface is denoted by \( R \). Thus, the thickness of the liquid film is given by \( h = R - R_n \) (see Fig. 1). Finally, \( L \) denotes the outmost radius of the entire system. \( L \) can be chosen in such a way that beyond \( L \) the physical density of vapor is nearly uniform (i.e., \( \rho_1 \)).

The supersaturation of the vapor is characterized by the chemical potential \( \mu \). At the fixed temperature, the vapor density \( \rho_1 \) is determined solely by \( \mu \), and so is the density of the bulk liquid \( \rho_2 \). For the open system, the grand thermodynamic potential is given by

\[
\Omega = -p_2 \frac{4\pi}{3}(R^3 - R_n^3) - p_1 \frac{4\pi}{3}(L^3 - R_n^3)
\]

\[+ 4\pi R_n^2 \sigma_{32}(R_n) + 4\pi R^2 \sigma_{21}(R) + \tilde{\Omega}(h),\]

(1)

where \( p_2 \) is the normal pressure of the uniform liquid film (with the density \( \rho_2 \)), \( p_1 \) is the pressure of the vapor (with the density \( \rho_1 \)), \( \sigma_{32}(R_n) \) is the surface tension of the solid–liquid interface, which depends on the curvature and the choice of the dividing surface \( R_n \), and \( \sigma_{21}(R) \) is the surface tension of the liquid–vapor interface, which also depends on the curvature and choice of the dividing surface \( R \). Both \( \sigma_{32}(R_n) \) and \( \sigma_{21}(R) \) are defined such that they are independent of the thickness of the liquid film. In reality, this would...
be true only if the film is thick so that the physical density of the film is nearly \( p_2 \). Equation (1) does not include the thermodynamic potential of the solid particle since it stays constant for all changes in the system.

The last term in Eq. (1), \( \Omega(h) \), is a function of the thickness of liquid film \( h \). It approaches zero as \( h \) goes to infinity. Assuming the spherical symmetry \( V \) can be written as the integral from some volume density \( \tilde{\omega}(r) \)

\[
\tilde{\Omega}(h) = 4\pi \int_{R}^{L} r^2 \tilde{\omega}(r) dr = 4\pi \int_{R, h}^{L} r^2 \tilde{\omega}(r) dr,
\]

where the integration is taken from \( R \) to \( L \), due to the removal of the bulk liquid from \( R \) to \( L \), which creates the liquid film with a finite thickness. Thus, Eq. (1) can be rewritten as

\[
\Omega + \frac{4\pi}{3} L^3 p_1 = -\frac{4\pi}{3} R^3(p_2 - p_1) + \frac{4\pi}{3} R^3 p_2 + 4\pi R^2 \sigma_{32}(R_n) + 4\pi R^2 \sigma_{21}(R) + 4\pi \int_{R}^{L} r^2 \tilde{\omega}(r) dr.
\]

Taking a partial derivative over \( R \) on Eq. (3) under the condition of fixed \( \mu \) and \( R_n \), and noting that \( \Omega, p_1, p_2, \) and \( \sigma_{32}(R_n) \) do not depend on \( R \), we obtain

\[
0 = -4\pi R^2(p_2 - p_1) + 8\pi R \sigma_{21}(R) + 4\pi R^2 \frac{\partial \sigma_{21}}{\partial R} + 4\pi \int_{R}^{L} r^2 \tilde{\omega}(r) dr,
\]

or

\[
p_2 - p_1 = \frac{2\sigma_{21}(R)}{R} + \frac{\partial \sigma_{21}}{\partial R}(R) - \tilde{\omega}(R_n + h).
\]

Equation (5) can be considered as the generalized Laplace equation in the case of heterogeneous nucleation.

The second important thermodynamic equation is the generalized Gibbs–Duhem equation, which can be derived by taking the differential of \( \Omega \) [Eq. (1)], under the condition of fixed temperature and total volume of the system

\[
d\Omega = -4\pi p_2 (R^2 dR - R_n^2 dR_n) - V_2 dp_2 + 4\pi p_1 R^2 dR - V_1 dp_1 + 8\pi R_n \sigma_{32} dR_n + 4\pi R_n^2 \sigma_{32} + 8\pi R \sigma_{21} dR + 4\pi R^2 d\sigma_{21} - 4\pi R^2 \tilde{\omega}(R) dR,
\]

where \( V_1 \) and \( V_2 \) are the volume of the vapor and the liquid, respectively. On the other hand, we have

\[
d\Omega = -Nd\mu = -(N_{32} + N_2 + N_{21} + N_1) d\mu,
\]

where \( N \) is the total number of molecules (excluding that of the solid particle) in the system, which is the sum of the molecules in the liquid film \( N_2 \), vapor \( N_1 \), and two interfacial regions \( N_{32} \) and \( N_{21} \). Combining Eq. (6) with Eq. (7) and noting that \( dR_n = 0 \) (for fixed solid–particle size), \( V_2 dp_2 = N_2 d\mu \) (or \( dp_2 = p_2 d\mu \)) and \( V_1 dp_1 = N_1 d\mu \) (or \( dp_1 = p_1 d\mu \)), we obtain

\[
-p_2 - p_1)4\pi R^2 dR + 4\pi R^2 d\sigma_{32} + 4\pi R^2 d\sigma_{21} + 8\pi R \sigma_{21} dR - 4\pi R \tilde{\omega}(R_n + h) dR + N_2 d\mu + N_{21} d\mu = 0.
\]

Substituting the generalized Laplace equation (5) into Eq. (8) results in the generalized Gibbs–Duhem equation

\[
-4\pi R^2 \frac{\partial \sigma_{21}}{\partial R} dR + 4\pi R^2 d\sigma_{21} + 4\pi R_n^2 \sigma_{32} + N_2 d\mu + N_{21} d\mu = 0.
\]

Equation (9) can be further separated into two equations

\[
d\sigma_{32} = -\Gamma_{32} d\mu,
\]

and

\[
d\sigma_{21} - \frac{\partial \sigma_{21}}{\partial R} dR = -\Gamma_{21} d\mu.
\]

by defining two adsorptions, \( \Gamma_{32} \) and \( \Gamma_{21} \). \( \Gamma_{32} = N_2 / 4\pi R_n^2 \) is the adsorption of the liquid on the surface of the solid particle, and \( \Gamma_{21} = N_2 / 4\pi R^2 \) is the adsorption at the liquid–vapor interface.

The generalized Laplace equation (5) and generalized Gibbs–Duhem equations (10) and (11) are key thermodynamic equations for the study of heterogeneous nucleation. We note that in our consideration \( \sigma_{32} \) and \( \sigma_{21} \) in these equations depend only on the curvature of the droplet, but not on the thickness of the liquid film. Only \( \tilde{\omega}(R_n + h) \) in Eq. (5) depends on the thickness \( h \). The physical significance of the free-energy density \( \tilde{\omega}(R_n + h) \) can be better illustrated from the limiting case of the liquid film (with thickness \( h \)) near a planar solid surface. In this limit the radial variable \( r \) can be replaced by \( z = r - R_n \), where the \( z \) axis is perpendicular to the solid surface with the origin at this surface. Thus, \( \tilde{\omega}(r) \) becomes \( \tilde{\omega}(z) = \lim_{z \to 0^-} \tilde{\omega}(r) \). In fact, we will restrict our attention to that type of particles for which the solid–liquid interaction potential depends only on the distance from the particle surface. For these particles, the replacement \( r \) by \( z \) is always valid.

Note that in the limiting case of planar liquid–vapor interface \( \sigma_{21} \) is independent of the curvature, namely, \( \sigma_{21}(R) \big|_{R=\infty} \) \( \sigma_{21}(R) \big|_{R=\infty} \). Let \( z_0 = |R_n - R_n| \). Equations (5), (10), and (11) then become

\[
p_2 - p_1 = -\tilde{\omega}(z_0 + h),
\]

\[
d\sigma_{32} = -\Gamma_{32} d\mu,
\]

and

\[
d\sigma_{21} = -\Gamma_{21} d\mu,
\]

respectively. Here, the bulk vapor pressure \( p_1 \) is also the normal component of pressure tensor at the interface and \( p_2 \) is the pressure of the bulk uniform liquid at the same \( \mu \). This means that \( p_1 - p_2 \) is just the Derjaguin’s disjoining pressure \( \Pi(h) \) for the planar liquid film; thus, \( \tilde{\omega}(z_0 + h) = \Pi(h) \) according to Eq. (12). \( \Pi(h) \) can be considered as a sum of several components:

\( \Pi(h) \) some due to the overlapping of the interfacial layers of the thin liquid film while others due to the interactions between the solid surface and the liquid film. The \( h \) dependence of \( \Pi \) is the key characteristic of the liquid
film needed to develop theory of heterogeneous nucleation on solid surface. This dependence cannot be given from the classical nucleation theory. DFT, on the other hand, can yield $\Pi(h)$, and numerical results will be given in the next section.

III. PROPERTIES OF THE LIQUID FILM NEAR PLANAR SOLID SURFACE: DFT, MODEL SYSTEM, AND THICKNESS DEPENDENCE

Let us first briefly summarize several main aspects of the WDA-DFT.\cite{10,11} Let $w(r_1, r_2) = w(r_{12})$ represent the pairwise interaction molecular potential for the simple nonpolar molecules. In this case the free-energy functional of nonuniform system near planar solid surface (with the random-phase approximation) is given by\cite{12–14}

$$ F[\rho] = \int dr f_{id}(\rho(z)) + \int dr \rho(z) \Delta \psi_h(\rho(z)) + \frac{1}{2} \int dr_1 dr_2 w_p(r_{12}) \rho(z_1) \rho(z_2), $$

(15)

where $z$ is the distance from the solid surface, $w_p(r_{12})$ is the small attractive part of interaction potential, and $f_{id}(\rho)$ is the free-energy density of the ideal gas. $\Delta \psi_h(\rho)$ is the excess free-energy density, and it can be calculated accurately via the Carnahan–Starling\cite{22} formula $\Delta \psi_h(\rho) = k_B T \eta(4 \pi \rho^3/3 - 3 \eta)/(1 - \eta)^2$, where $k_B$ is the Boltzmann constant, $T$ is the temperature, and $\eta = \pi \rho d^2/6$ ($d$ is the hard-sphere diameter and $\rho$ is the density). In Eq. (15), $\Delta \psi_h(\rho)$ is a function of the weighted density $\bar{\rho}(z)$. The latter can be determined by averaging the true local density $\rho(z)$ over certain local volume. Following Tarazona,\cite{10,11} we have

$$ \bar{\rho}(z_1) = \int dr_2 \rho_0(r_{12}, \bar{\rho}(z_1)), $$

(16)

where the weighting function $\omega$ is chosen in the same way as in Refs. 10 and 11.

In the grand canonical ensemble, the grand thermodynamic potential is given by

$$ \Omega[\rho] = F[\rho] + \int dr_1 \rho(z_1) V_{ext}(z_1) - \mu \int dr_1 \rho(z_1), $$

(17)

where $V_{ext}(z_1)$ is the external potential (here, due to the solid surface). The equilibrium density profile is determined from the variational principle $\delta \Omega[\rho] / \delta \rho = 0$, which gives

$$ \rho(z_1) = \exp \left[ - \frac{1}{k_B T} \int dr_2 \rho(z_2) \Delta \psi_h(\bar{\rho}(z_2)) \right. \right.$$

$$ \times \frac{\omega(r_{12}, \bar{\rho}(z_1))}{1 - \bar{\rho}_1(z_2) - 2 \bar{\rho}_2(z_2) \bar{\rho}(z_2) + \Delta \psi_h(\bar{\rho}(z_1))} + \int dr_2 w_p(r_{12}) \rho(z_2) + V_{ext}(z_1) - \mu \left. \right] \right], $$

(18)

where $\bar{\rho}_1$ and $\bar{\rho}_2$ are defined in Refs. 10 and 11. The density profile $\rho(z)$ of the liquid film near a solid surface can be determined by solving the Eq. (18). To this end, we used an iteration method suggested by Tarazona.\cite{10}

The model system is chosen to be the Lennard-Jones (LJ) fluid near a $9-3$ LJ smooth solid surface. In the framework of Weeks–Chandler–Anderson\cite{23} perturbation scheme, we have

$$ w_p(r_{12}) = \begin{cases} \frac{-\epsilon_{LJ}}{\bigr( \sigma/r_{12} \bigr)^{12} - (\sigma/r_{12})^6}, & r_{12} < 2^{1/6} \sigma, \\ 4 \frac{\epsilon_{LJ}}{\bigr( \sigma/r_{12} \bigr)^{12}} - (\sigma/r_{12})^6, & r_{12} > 2^{1/6} \sigma, \end{cases} $$

(19)

where $\epsilon_{13}$ and $\sigma$ are the LJ parameters. The diameter of hard spheres (reference system) is related to $\sigma$, i.e., $d = (a_1 T + a_3)/(a_2 T + a_3) \sigma$, where the constants $a_1$, $a_2$, $a_3$, and $a_4$ are given in Ref. 24. The solid-surface potential\cite{18} is given by

$$ V_{ext}(z) = - \rho_3 \left( \frac{u_2}{z} + \frac{u_9}{z} \right), $$

(20)

where $\rho_3 = 12 d^3$ is the density of the solid surface and coefficients $u_3$ and $u_9$ can be found as a result of summation for pairwise liquid–wall interactions over lattice structure of the wall. Following Getta and Dietrich\cite{18} we use $u_3 = 2.348 \epsilon_{13} \sigma^6$ and $u_9 = -5.326 \epsilon_{13} \sigma^9$. For the numerical calculation, $V_{ext}(z)$ is set to be infinity for $z < 0.84d$. The two reduced temperatures considered here are $T^* = k_B T / \epsilon_{13} = 0.7$ and 0.9; both are above the wetting temperature of the system as well as the surface critical temperature.

Using the iteration procedure, we have calculated $\rho(z)$ for several given chemical potential $\mu$. The density profiles are shown in Fig. 2, which all exhibit the well-known oscillatory behavior near the solid surface. For $\mu = \mu_{\infty}$, the thickness $h$ becomes infinity. Note that $\mu_{\infty}$ can be determined from the condition $p_1 = p_2$. In the DFT, the bulk pressure is written as

$$ p = p_h(\rho) - \frac{1}{2} \Psi \rho^2, $$

(21)
where \( p_h(p) \) is the pressure of the hard spheres \(^{22}\) and \( \Psi = -\int dr w(r) \). For \( \mu < \mu_c \), the liquid film has a finite thickness \( h \), and \( p_1 \) and \( p_2 \) differs by \( \Pi \), that is, the disjoining pressure.

Given the density profiles of the liquid films, we are ready to determine the thickness of the liquid film \( h \). For a planar liquid film near the solid surface, Eq. (1) can be written as

\[
\tilde{\Omega} = -p_2 h - p_1 (\tilde{L} - h - z_0) + \sigma_{32} + \sigma_{21} + \tilde{\Omega}(h)/A, \tag{22}
\]

where \( A \) is the surface area, \( \tilde{\Omega} = \Omega/A \), \( \tilde{L} \) denotes the outmost boundary of the system, and \( z_0 \) is the distance between the solid–liquid dividing surface and the solid surface. The last term in Eq. (22) is

\[
\tilde{\Omega}(h)/A = \frac{4\pi}{A} \int_{R_n + h}^{\tilde{L}} r^2 \tilde{\omega}(r) dr
\]

\[
= \frac{4\pi}{A} \int_{z_0 + h}^{\tilde{L}} (R_n - z_0 + z)^2 \tilde{\omega}(z) dz
\]

\[
= \frac{4\pi R_n^2}{A} \int_{z_0 + h}^{\tilde{L}} (1 + (z - z_0)/R_n)^2 \tilde{\omega}(z) dz
\]

\[
- \int_{z_0 + h}^{\tilde{L}} \tilde{\omega}(z) dz|_{R_n - z_0} = \int_{h}^{L - z_0} \Pi(h) d\tilde{h}. \tag{23}
\]

Using \( p_1 - p_2 = \Pi(h) \) and Eq. (23), we rewrite Eq. (22) as

\[
\tilde{\Omega} + p_1 (\tilde{L} - z_0) = \Pi(h) h + \sigma_{32} + \sigma_{21} + \int_{h}^{L - z_0} \Pi(h) d\tilde{h}. \tag{24}
\]

Although the left-hand side of Eq. (24) can be determined from the DFT, \( \sigma_{32} \), \( \sigma_{21} \), and \( h \) on the right-hand side are strongly dependent on the choice of the dividing surface.

For the liquid–vapor interface, we have chosen the equimolar dividing surface as the dividing surface so that \( \Gamma_{21} = 0 \). Thus, according to Eq. (14), \( \sigma_{21} \) will have a constant value regardless of \( \mu \), and this value is equal to the surface tension of the liquid–vapor interface \( \sigma_{21} = \Omega_{\infty} + p_1 \tilde{L} \) in the absence of the solid surface. For the solid–liquid interface, we have chosen the position of the dividing surface such that \( \Gamma_{32} \) is a constant. However, unlike \( \Gamma_{21} \), \( \Gamma_{32} \) cannot be zero because there is always some liquid or vapor (even when \( h = 0 \)) adsorbed on the solid surface. To determine \( \Gamma_{32} \) and \( z_0 \), we have used two limiting cases of \( h \), one for \( h \) approaching infinity and the other for \( h \) approaching zero. The first case occurs when \( \mu = \mu_c \) (see Fig. 2). The number of particles per unit surface area is given by

\[
\int_{0}^{\tilde{L}} \rho(z) dz|_{\mu = \mu_c} = \Gamma_{32} + \rho_{2\infty} (\tilde{L} - z_0), \tag{25}
\]

where \( \rho_{2\infty} \) is the bulk density of the liquid at \( \mu = \mu_c \). The second limiting case occurs when \( \mu = \mu_s \), the chemical potential at liquid spinodal. The value of \( \mu_s \) can be calculated from the DFT. For \( \mu < \mu_c \), the bulk liquid phase does not exist, and thus \( p_2, p_2, \) and \( \Pi(h) \) are not defined. This means one has to set the thickness \( h = 0 \). In this case the number of particles per unit surface area is given by

\[
\int_{0}^{\tilde{L}} \rho(z) dz|_{\mu = \mu_s} = \Gamma_{32} + \rho_{2\infty} (\tilde{L} - z_0). \tag{26}
\]

The left-hand side of both Eqs. (25) and (26) can be evaluated using the DFT. Thus, the two unknowns \( \Gamma_{32} \) and \( z_0 \) can be determined by solving the coupled Eqs. (25) and (26). Once \( \Gamma_{32} \) and \( z_0 \) are known, we can define the thickness of the film \( h \) for a given \( \mu (\mu_s < \mu < \mu_c) \), that is,

\[
\frac{\int_{0}^{\tilde{L}} \rho(z) dz|_{\mu = \mu_c}}{\rho_{2\infty} - \rho_1} = \frac{\Gamma_{32} + \rho_{2\infty} (\tilde{L} - z_0)}{\rho_2 - \rho_1}. \tag{27}
\]

With \( h \) defined, we turn to the main objective of this section, the thickness dependence of \( \sigma_{32} \) and \( \Pi \). Integrating Eq. (13) with \( \Gamma_{32} \) fixed, we obtain

\[
\sigma_{32} = \sigma_{32}^{\infty} - \Gamma_{32} (\mu - \mu_c), \tag{28}
\]

where \( \sigma_{32}^{\infty} = \tilde{\Omega} + p_{2\infty} (\tilde{L} - z_0) \) is the solid–liquid surface tension when \( h \rightarrow \infty \).

The dependence of \( \Pi \) on \( h \) for a given \( \mu \) (between \( \mu_s \) and \( \mu_c \)) is shown in Fig. 3. Indeed, \( \Pi(h) \) is an essential input in the heterogeneous nucleation theory. In the classical
heterogeneous nucleation theory, two commonly used approximations to \( \Pi(h) \) are the power-law approximation and the exponential approximation. The former is for relatively thick liquid films, while the latter is for the thin structural films. In the case of nonpolar LJ fluid, the power-law approximation to \( \Pi(h) \) is given by

\[
\Pi(h) \approx \frac{B}{(z_0 + h)^\tau},
\]

where \( B \) is the Hamaker constant. However, the classical nucleation theory does not give this constant. In Ref. 18, a formula is given to estimate \( B \) based on the sharp-kink approximation to the density profile. According to this formula and in our notation, \( B \) is given by

\[
B = (\rho_{\infty} - \rho_1) \rho_1 u_1 (\rho_2 + \rho_3),
\]

where the subscript \( \infty \) refers to \( \mu = \mu_{\infty} \), and \( t_3 = \frac{-2\Psi / 3\pi \sigma^3}{64\sqrt{27\sigma^6 e_{11}}} \) [using Eq. (19)]. To compare our result of \( \Pi(h) \) to that of the power-law approximation, we set \( B \) as an independent parameter to fit the calculated \( \Pi(h) \). The fitting shows that \( B \) is about 10% larger than that calculated from Eq. (30), indicating that Eq. (30) gives quite a good estimation of \( B \). We conclude that the power-law approximation is in good agreement with the DFT result for relatively thick liquid films, e.g., \( z > 5d \) (see Fig. 3).

On the other hand, the exponential approximation to \( \Pi(h) \) is given (in our notation) by

\[
\Pi(h) \approx \Pi \exp(-z - z_0/l),
\]

where \( \Pi \) is the disjoining pressure at the zero thickness \( (z = z_0) \), and \( l \) is the correlation length for the film near the solid particle. Clearly, \( l \) cannot be given from the classical heterogeneous nucleation theory. A fit of \( l \) to the DFT calculation yields \( l \approx 1.5d \). We also find \( l \) slightly increases with the temperature. Figure 3 shows that the exponential approximation to \( \Pi \) is in good agreement with \( \Pi \) calculated from the DFT for \( z_0 < z < 5d \).

**IV. CHEMICAL POTENTIAL OF THE LIQUID CONDENSATE**

Calculation of the barrier height to nucleation requires the chemical potential of the liquid condensate as a function of the droplet’s size \( R \) as well as the number of particles in the droplet or in the adsorbed film, \( \nu \). In this section, we will find the \( R \)- and \( \nu \)-dependence based on the DFT model.

**A. Chemical potential of liquid condensate and \( R \) dependence**

We start from Eqs. (5) and (11). The surface tension \( \sigma_{21}(R) \) appears in both equations. Since we consider only the condensation on mesoscopic solid particles, \( R \) is large enough to warrant the use of the Tolman formula

\[
\sigma_{21} = \sigma_{21}^\infty \left(1 - \frac{2\delta_\infty}{R}\right),
\]

where \( \sigma_{21}^\infty \) is the surface tension of the planar liquid–vapor interface in the absence of the solid particle, and \( \delta_\infty \) is the the Tolman length when \( R \to \infty \). Previous DFT studies have shown that (i) \( \sigma_{21}(R) \) is not a monotonic function of \( R \), (ii) \( \sigma_{21} \) approaches zero as \( R \to 0 \), (iii) Eq. (32) is applicable only when \( R \) is at least greater than \( 5d \), and (iv) \( \delta_\infty \) is a small negative constant. For the mesoscopic solid particle considered here, the condition \( R > 5d \) is well satisfied.

Taking the dividing surface to be the equimolar dividing surface so that \( \Gamma_{21} = 0 \), and substituting Eq. (32) into Eq. (11) gives

\[
\frac{\partial \sigma_{21}}{\partial \Gamma} = \frac{d \sigma_{21}}{d \Gamma} = \frac{d}{d \Gamma} \left[ \sigma_{21}^\infty \left(1 - \frac{2\delta_\infty}{R}\right) \right] = \frac{2\sigma_{21}^\infty \delta_\infty}{R^2}.
\]

Substituting Eq. (33) into the Laplace equation (5) gives

\[
p_2 - p_1 = \frac{2\sigma_{21}^\infty}{R^2} \left(1 - \frac{\delta_\infty}{R}\right) - \Pi(h).
\]

It is well known that the compressibility correction is in the same order as the curvature correction. Therefore, we should also take into account the compressibility corrections which were not included in the classical consideration.

In Eq. (34), the pressure difference \( p_2 - p_1 \) can be calculated via the compressibility route. We start from the density of the liquid, which can be given approximately by

\[
p_2 = p_{\infty} + p_2 = p_{\infty} + \rho_{\infty}^2 \chi_2 \Delta \mu,
\]

where \( p_{\infty} \) is the density of the uniform liquid at \( \mu = \mu_{\infty} \), \( \chi_2 \) is the compressibility of the liquid, and \( \Delta \mu = \mu - \mu_{\infty} \). We can show from the DFT that Eq. (35) provides an accurate estimation for \( p_2 \) except when \( \mu \) is very close to \( \mu_{\infty} \), where the dependence \( p_2 \) on \( \mu \) becomes nonlinear. Integrating Eq. (35) over \( \mu \) yields the pressure of the liquid

\[
p_2 - p_1 = p_{\infty} - p_{\infty} + \rho_{\infty} \Delta \mu + \frac{1}{2} \rho_{\infty}^2 \chi_2 \Delta \mu^2,
\]

where \( p_{\infty} \) is the pressure of the liquid at \( \mu = \mu_{\infty} \), and \( \rho_{\infty} = p_{\infty} \). Thus, the second formula for \( p_2 - p_1 \) is

\[
p_2 - p_1 = p_{\infty} - p_{\infty} + \rho_{\infty} \Delta \mu + \frac{1}{2} \rho_{\infty}^2 \chi_2 \Delta \mu^2.
\]

In Eq. (37), the term \( p_{\infty} - p_{\infty} \) can be neglected compared to the next two terms as \( p_{\infty} \ll p_{\infty} \). The latter condition is satisfied for the LJ system at the reduced temperatures 0.7 and 0.9 since both are far below the critical temperature.

Combining Eq. (37) with Eq. (34) and neglecting \( p_{\infty} - p_{\infty} \) results in a quadratic equation (38) for \( \Delta \mu \)

\[
\frac{1}{2} \rho_{\infty} \chi_2 \Delta \mu^2 + \rho_{\infty} \Delta \mu - \frac{2\sigma_{21}^\infty}{R^2} \left(1 - \frac{\delta_\infty}{R}\right) + \Pi(h) = 0.
\]

(38)

Since \( \delta_\infty / R, \sigma_{21}^\infty \chi_2 / R, \) and \( \Pi \chi_2 \) in Eq. (38) are all small parameters due to the mesoscopic size of the droplet \( R \) as well as the small value of compressibility of the liquid, the solution of the quadratic equation of \( \Delta \mu \) can be expressed in terms of these small parameters to the first order, that is

\[
\Delta \mu = \frac{1}{\rho_{\infty}} \left[ \frac{2\sigma_{21}^\infty}{R^2} \left(1 - \frac{\delta_\infty + \sigma_{21}^\infty \chi_2 / R}{R} + \Pi \chi_2 \right) - \Pi - \chi_2^2 \frac{R^2}{2} \right].
\]

(39)

Equation (39) is an important result of this paper. It gives the chemical potential of liquid condensate as a function of the droplet size \( R \), which will be used later to calculate the bar-
rrier to nucleation. It can be reduced to the classical equation by removing curvature and compressibility corrections. Comparing the DFT results of $\Delta \mu(h)$ in the planar limit with those by using Eq. (39) (analytical planar expression based on the disjoining pressure and compressibility corrections) indicates that Eq. (39) provides quite a good estimation of the chemical potential as function of the film thickness. Indeed, at low temperatures the difference is negligible except for $h<1.5d$, for which the difference is still less than a few percent.

Note that several quantities in Eq. (39) can be obtained directly from experiments. These include the disjoining pressure $\Pi(h)$, the liquid compressibility $\chi_2$, the liquid density $\rho_{2n}$, and the planar surface tension $\sigma_{21}$. Only the Tolman length $\delta_\infty$ has not yet been measured because it is on the order of molecular length scale. Of course, all these quantities can also be calculated from the DFT. Appendix A describes how the surface tension and the Tolman length can be determined based on the WDA-DFT. On the other hand the classical nucleation theory can only provide some estimation for the chemical potential $\Delta \mu$; neither $\Pi(h)$ nor $\sigma_{21}$ and $\delta_\infty$ can be determined in the framework of this theory.

Once the $\sigma_{21}$ and $\delta_\infty$ are determined from the WDA-DFT, the chemical potential of the liquid condensate as a function of droplet radius $R$ can be evaluated from Eq. (39). Results are shown in Fig. 4 for $R_n>5d$. We find that the $R$ dependence is not monotonic but has a maximum at a scaled chemical potential $b_m$ at $R=R_m$ (hereafter, we use the dimensionless chemical potential $b=\Delta \mu/k_B T$). Similar $R$ dependence was found from the classical heterogeneous nucleation theory, although empirical parameters were used.

Let $b_1$ be the dimensionless chemical potential of the metastable vapor. If $0<b_1<b_m$, the equation $b(R)=b_1$ has two solutions. One solution is $R=R_2$, for which $db(R)/dR>0$. It corresponds to a stable droplet of the liquid condensate forming on the solid particle, and this droplet is in chemical equilibrium with the surrounding supersaturated vapor. Another solution is at $R=R_5$, for which $db(R)/dR<0$. It corresponds to the critical droplet of the liquid condensate with the solid particle at the center, and this droplet is in unstable equilibrium with the surrounding supersaturated vapor. The equilibrium droplet cannot grow in size. To grow, the droplet size should be larger than $R_5$ to overcome the barrier to nucleation. Finally, if $b_1>b_m$ the equation $b(R)=b_1$ does not have any solutions and the heterogeneous nucleation becomes barrierless.

We close this subsection by noting that at the maximum value of $b$ the corresponding droplet size $R_m$ is always in the region of thick films (see Fig. 4) for all solid particle sizes $R_n$ considered. Therefore, at $R_m$, the disjoining pressure $\Pi(R_m)$ can be well described by the power-law approximation [Eq. (29)]

\[ b(R) = \frac{4\pi}{3} (R^3 - R_n^3) \rho_2 + 4\pi R_n^2 \Gamma_{32} + 4\pi R^2 \Gamma_{21}, \]  

where $\rho_2$ can be determined from Eq. (35). Note that we have chosen the liquid--vapor dividing surface such that $\Gamma_{21}=0$. We have also chosen the solid--liquid dividing surface such that $\Gamma_{32}$ is a constant for $R>R_n$. This constant can be found from Eqs. (25) and (26). For mesoscopic solid particles, we assume the adsorption $\Gamma_{32}$ is the same as that in the planar case. However, for $R=R_n$, we know that $h=0$ and $\Gamma_{32}=\Gamma_{31}$ at $\mu=\mu_s$. If $\mu<\mu_s$, the adsorption $\Gamma_{32}$ is not well defined and $\Gamma_{31}$ cannot be considered as a constant. In fact, whenever $\mu<\mu_s$ and the film has a zero thickness ($h=0$), which means that the liquid condensate no longer exists except for an adsorbed film on the surface of the solid particle. Combining Eqs. (35), (39), and (40) and taking into account both liquid condensate and adsorbed film and keeping only first-order terms, we obtain

\[ b(R) = \frac{4\pi}{3} (R^3 - R_n^3) \rho_2 + 4\pi R_n^2 \Gamma_{32} + 4\pi R^2 \Gamma_{21}, \]
$$\nu(R) = \frac{4\pi}{3} (R^3 - R_n^3) \rho_2 x_2 \left( 1 + \rho_2 x_2 \frac{2\sigma_{21}}{R} - \Pi(h) \right) + 4\pi R_n^2 \Gamma_{31}, \quad R > R_n$$

$$\nu(\Gamma_{31}) = 4\pi R_n^2 \Gamma_{31}, \quad R = R_n.$$  \hspace{1cm} (41)

Consequently, for \(\mu < \mu_z\), \(\nu\) no longer depends on \(R\) but only on \(\Gamma_{31}\), which changes from zero to a finite value when \(h = 0\).

**C. Dependence of \(\nu\) on the gas adsorption \(\Gamma_{31}\)**

For the planar solid surface \((R_n \to \infty)\), the gas adsorption \(\Gamma_{31}\) can be calculated for given \(\mu < \mu_z\) from the equation

$$\Gamma_{31}(\mu) = \int_0^h \rho(z) dz - \rho_1(L - z_0), \hspace{1cm} (42)$$

where \(z_0\) is the position of the dividing surface. Meanwhile, the pressure of an undersaturated vapor, \(p_1\), can be calculated from Eq. (21), or approximately from the ideal-gas law because \(p_1\) is very small. Combining Eq. (21) with Eq. (42) for \(\mu\) gives the gas-adsorption isotherm \(p_1 = g(\Gamma_{31})\), where \(g\) is some function of \(\Gamma_{31}\). Figure 5 shows \(\Gamma_{31}\) versus \(p_1\) (for the ideal gas \(p_1\) and the scaled pressure \(p_1/k_BT\) are the same), which shows \(\Gamma_{31}\) is a stepwise monotonic function. This type of isotherm has been classified by earlier workers as one of the several typical isotherms for the gas adsorption on the solid surface. The stepwise nature of this isotherm stems from the oscillatory behavior of the density profile of the adsorbed film. Note that in the classical theory the linear or Henry's law was used, that is,

$$\Gamma_{31} = K_T \rho_1, \hspace{1cm} (43)$$

where \(K_T\) is the Henry’s law constant.

In the case of \(R = R_n\) and \(\mu < \mu_z\), the grand potential of the system is given by

$$\Omega = -p_1 \frac{4\pi}{3} (L^3 - R_n^3) + 4\pi R_n^2 \sigma_{31}, \hspace{1cm} (44)$$

where \(\sigma_{31}(R_n) = \sigma_{31}(\tilde{R}_n, z_0)\) is the surface tension of solid-vapor interface, which depends on both the curvature of the particle \(\tilde{R}_n\) and the position of the dividing surface \(z_0\). Since \(\Omega\) itself is independent on the choice of \(z_0\), taking derivative over \(z_0\) on Eq. (44) gives

$$p_1 = -\frac{2\sigma_{31}}{R_n} - \frac{\partial \sigma_{31}}{\partial z_0}. \hspace{1cm} (45)$$

Equation (45) is analog to the Laplace equation for liquid-vapor surfaces. We assume the two variables of \(\sigma_{31}(\tilde{R}_n, z_0)\) are separable, i.e., \(\sigma_{31}(\tilde{R}_n, z_0) = \sigma_{31}(z_0)c(\tilde{R}_n)\), which becomes exact as \(\tilde{R}_n \to \infty\) where the function \(c(R_n)\) approaches 1. Thus, for the planar solid surface \((R_n \to \infty)\), Eq. (45) becomes

$$p_1 = -\frac{\partial \sigma_{31}^\infty}{\partial z_0}, \hspace{1cm} (46)$$

or

$$g(\Gamma_{31}) = -\frac{\partial \sigma_{31}^\infty}{\partial z_0}. \hspace{1cm} (47)$$

since \(p_1 = g(\Gamma_{31})\). Combining Eq. (47) with Eq. (45) gives

$$p_1 = -\frac{2\sigma_{31}}{R_n} + c(\tilde{R}_n)g(\Gamma_{31}). \hspace{1cm} (48)$$

Moreover, because the vapor is in equilibrium with the adsorbed film, we have \(p_1 = p_1^\infty \exp(b(\nu))\), assuming the vapor is an ideal gas. Here, \(b(\nu)\) is the scaled chemical potential of the adsorbed film. Combining the equilibrium equation with Eq. (48), we obtain

$$b(\nu) = \ln \left( -\frac{2\sigma_{31}}{R_n p_1^\infty} + \frac{c(\tilde{R}_n)g(\Gamma_{31})}{p_1^\infty} \right). \hspace{1cm} (49)$$

In Eq. (49), two unknowns remain to be determined: (1) \(\sigma_{31}\) and (2) \(c(\tilde{R}_n)\). First, combining Eqs. (44) and (45) with the thermodynamic relation \(d\Omega = -N d\mu = - (N_1 + N_{31}) d\mu\) and \(dp_1 = \rho_1 d\mu\) results in

$$d\sigma_{31} = -\frac{\partial \sigma_{31}}{\partial z_0} dR_n - \Gamma_{31} d\mu. \hspace{1cm} (50)$$

![FIG. 5. Adsorption isotherms for the LJ fluid near the planar solid surface. The scaled adsorption \(\Gamma_{31}^* = \Gamma_{31} \pi d^2/48\) vs scaled vapor density \(\eta_1 = \rho_1 \pi d^2/48\). The horizontal line shows the value of \(\Gamma_{31}^*\). (a) \(T^* = 0.7\); (b) \(T^* = 0.9\).](image-url)
Because the size of the solid particle and the position of the dividing surface is fixed, Eq. (50) is reduced to
\[
d\sigma_{31} = -\Gamma_{31} \kappa B d\sigma(R).
\]
Using Eqs. (49) and (51), we eliminate the first unknown, \(\sigma_{31}\), and obtain a differential equation for \(b(\nu)\)
\[
\frac{d\nu}{d\Gamma_{31}} = \frac{c(\tilde{R}_{n})}{p_{1\infty}} \frac{d\Gamma_{31}}{\Gamma_{31}} \frac{1}{\exp(b(\nu)) - 2\Gamma_{31}/R_{n} p_{1\infty}},
\]
where \(\nu = 4\pi R^{2}_{n} \Gamma_{31}\) [see Eq. (41)]. Next, we determine \(c(\tilde{R}_{n})\). To this end, we follow the method introduced in Ref. 5 by using the so-called patching condition
\[
d\nu/d\nu|_{\Gamma_{31}=\Gamma_{32}} = d\nu/d\nu|_{R=R_{n}}.
\]
The derivation of \(c(\tilde{R}_{n})\) is given in Appendix B.

Note that if the Henry’s law isotherm is substituted for \(g(\Gamma_{31})\) (which was used in the classical nucleation theory) Eq. (52) will have a simple analytic solution, \(d\nu/d\nu|_{\Gamma_{31}=\Gamma_{32}} = d\nu/d\nu|_{R=R_{n}}\). With the parabolic approximation, the number of oscillations about the straight line. Let
\[
\frac{d\nu}{d\nu}|_{\nu_{m}} = \frac{2}{\kappa(\nu_{m})}.
\]
This equation is easier to solve than Eq. (52) as the latter contains a near-divergent term \(\ln(a(\tilde{R}_{n})\Gamma_{31})\). Numerical solution of Eq. (52) is obtained as well as that of \((b(\nu))\) of Eq. (53).

With both Eq. (39) for \(\nu = 4\pi R^{2}_{n} \Gamma_{31} \leq 4\pi R^{2}_{n} \Gamma_{32}\) and Eq. (53) for \(\nu = 4\pi R^{2}_{n} \Gamma_{31} \leq 4\pi R^{2}_{n} \Gamma_{32}\), we obtain the chemical potential \(b(\nu)\) over the entire range of \(\nu\). Figure 6 shows a plot of \(b(\nu)\) versus \(\nu\) for given \(R_{n}\) temperatures, where \(\nu=0\) corresponds to the bare solid particle. For adsorbed films, weak oscillations appear on the \(b(\nu)\) curves [see Figs. 6(a) and 6(c)], due to the stepwise structure of the adsorption isotherm. For thicker liquid films, these oscillations do not appear.

D. Chemical potential for barrierless and near-threshold nucleation

As mentioned above, a key feature in the \(b(R)\) or \(b(\nu)\) curves [Figs. 6(b) and 6(d)], is the existence of a maximum
\(b_{m}\) at \(R_{m}\) or \(\nu_{m}\). For the purpose of discussing heterogeneous nucleation, let us define the threshold value \(b_{th}=\gamma_{m}\) of chemical potential of the vapor. In the overthreshold region \(b_{1} > b_{th}\), the heterogeneous nucleation process becomes barrierless. In the underthreshold region \(0 < b_{1} < b_{th}\) the barrier height to nucleation depends on the value of \(b_{1}\). In practice, however, the near-threshold region in which \(b_{1}\) close to \(b_{th}\) has received more attention because in this region the rate of nucleation can be conveniently measured.

A description of the near-threshold region has been given in Refs. 2 and 4. Following Ref. 2, we will use an \(\epsilon\) parameter (0 < \(\epsilon < 1\)) to characterizes how far \(b_{1}\) is from \(b_{th}\), that is,
\[
b_{1} = b_{th}(1 - \epsilon).
\]
The barrierless nucleation occurs when \(\epsilon = 0\) while the near-threshold nucleation is denoted by \(\epsilon \ll 1\). In this region the chemical potential of the liquid condensate can be expanded up to the second order (the parabolic approximation) about \(\nu_{m}\)
\[
b(\nu) = b_{th} - \frac{1}{2} \left[ \frac{d^{2}b(\nu)}{d\nu^{2}} \right]_{\nu_{m}} (\nu - \nu_{m})^{2},
\]
where the first-order term vanishes because \(d\nu/d\nu|_{\nu_{m}} = 0\). Validity of the parabolic approximation can be examined from the condition
\[
\frac{1}{3} \left( \frac{(\nu - \nu_{m})d^{2}b(\nu)/d\nu^{2}}{d\nu^{2}b(\nu)/d\nu^{2} \left|_{\nu_{m}} \right.} \right) \ll 1,
\]
that is, when the third-order term is much smaller than the second one. With the parabolic approximation, the number of molecules for a given \(\epsilon\) in the equilibrium and critical droplet are given by
\[
\nu_{c} = \nu_{m} - (2\epsilon b_{th}) \left[ \frac{d^{2}b(\nu)}{d\nu^{2}} \right]_{\nu_{m}}^{1/2},
\]
\[
\nu_{c} = \nu_{m} + (2\epsilon b_{th}) \left[ \frac{d^{2}b(\nu)}{d\nu^{2}} \right]_{\nu_{m}}^{1/2},
\]
respectively, and with which the condition Eq. (57) becomes
\[
\frac{1}{3} \left( \frac{(2\epsilon b_{th})^{1/2} \left[ \frac{d^{2}b(\nu)}{d\nu^{2}} \right]_{\nu_{m}}^{1/2}}{d\nu^{2}b(\nu)/d\nu^{2} \left|_{\nu_{m}} \right.} \right) \ll 1.
\]
Equations (55)–(59) form the basis for the description of the near-threshold region in the classical theory of heterogeneous nucleation.

Let us first determine \(\nu_{m}\) or \(R_{m}\) from \(d\nu/d\nu|_{\nu_{m}} = 0\) or from \(dR/dR|_{R=R_{m}} = 0\) with using Eq. (39). Note again that Eq. (39) involves a zero-order term as well as first-order terms of compressibility and curvature. To separate their contribution to \(R_{m}\), we write
\[
R_{m} = R_{m}^{(0)} (1 + \xi),
\]
where \(R_{m}^{(0)}\) denotes the solution of the equation with only the zero-order term, that is,
\[
\frac{d}{dR} \left( \frac{2\sigma_{21}}{R} - \Pi \right) = - \frac{2\sigma_{21}}{R_{m}^{2}} \frac{\partial \Pi}{\partial z} \bigg|_{R=R_{m}} = 0.
\]
\( z \) is a small correction to \( R_m^{(0)} \) by including the first-order terms in Eq. (39). Substituting Eq. (60) with the solution \( R_m^{(0)} \) from Eq. (51) into \( \frac{db(R)}{dR} \big|_{R_m=0} \) gives

\[
\zeta = -\frac{4 \sigma_{21}^\infty \delta_\infty}{R_m^{(0)} - 4 \sigma_{21}^2/2 R_m^{(03)} - \partial^2 \Pi/\partial z^2 - R_m^{(01)}}. \tag{62}
\]

Next, since \( R_m \) is in the region of thick films (Sec. IV A), the power-law approximation [Eq. (29)] can be used to evaluate \( \Pi \) in Eq. (61). As a result, the positive solution of the quadratic equation (61) is

\[
R_m^{(0)} = \bar{R}_n + \frac{1}{2} \sqrt{\frac{3 B}{2 \sigma_{21}}} + \sqrt{\bar{R}_n - \frac{3 B}{2 \sigma_{21}}} + \frac{3 B}{8 \sigma_{21}}. \tag{63}
\]

Substituting this zero-order solution into Eq. (62) gives the first-order correction

\[
\zeta = \frac{\delta_\infty}{R_m^{(0)}} - \frac{\bar{R}_n}{R_m^{(0)} + \bar{R}_n}. \tag{64}
\]

Finally, substituting Eqs. (60) and (64) into Eq. (41) gives

\[
\nu_m = 4 \pi R_n^2 \Gamma_{32} + \frac{4 \pi}{3} \rho_2 \delta_2 (R_m^{(03)} - R_n^3 + 3 \zeta R_m^{(01)}) \times \left( 1 + \chi_2 \delta_2 \frac{2 \sigma_{21}^2}{R_m^{(0)}} \Pi \big|_{R=R_m^{(0)}} \right)
= 4 \pi R_n^2 \Gamma_{32} + \frac{4 \pi}{3} \rho_2 \delta_2 (R_m^{(03)} - R_n^3)
\times \left( 1 + \frac{3 (R_m^{(0)} - \bar{R}_n) R_m^{(01)}}{(R_m^{(0)} + \bar{R}_n)(R_m^{(03)} - R_n^3)} \delta_\infty \right.
+ \left. \chi_2 \frac{2 \sigma_{21}^2}{R_m^{(0)}} \frac{2 R_m^{(0)} + \bar{R}_n}{3 R_m^{(03)} - R_n^3} \right).
\tag{65}
\]

Using \( R_m^{(0)} \) [Eq. (63)] and Eq. (29), we obtain the threshold chemical potential.
\[ b_{1n} = \frac{1}{\rho_2 z k_B T} \bigg( \frac{2 \sigma_{\infty}^2}{R_m^2} \bigg) \frac{2 R_m^{(0)} + \tilde{R}_n}{3 R_m^{(0)}} \left( 1 - \frac{3 \delta_n}{2 R_m^{(0)} + \tilde{R}_n} \right) - \frac{3 \sigma_{\infty}^2 x_2}{2 R_m^{(0)} + \tilde{R}_n} \bigg( \frac{4 \sigma_{\infty}^2}{R_m^{(0)} + \tilde{R}_n} \bigg) \left( \frac{9 R_m^{(0)} + \tilde{R}_n}{2 R_m^{(0)}} \right) \bigg). \]

(66)

Having derived \( \nu_m \), the validity condition of the parabolic approximation [Eq. (56)] can be examined by calculating the second and third derivative of \( b(\nu) \) at \( \nu_m \). Detailed expressions are given in Appendix C. Moreover, given Eqs. (66) and (C2), we can calculate the size of equilibrium cluster \( \nu_e \) and critical cluster \( \nu_c \) using Eq. (58). In Fig. 6, the parabolic approximation of \( b(\nu) \) [Eq. (56)] is also shown for the given \( \tilde{R}_n \) and temperatures. One can see that the approximation is quite good, particularly near \( \nu = \nu_m \), which is the near-threshold region in which we are interested.

V. FREE ENERGY OF DROPLET FORMATION AND THE BARRIER HEIGHT

The free energy of droplet formation and barrier height are key characteristics that control the rate of nucleation. In the last section we have derived the chemical potential as a function of the number of molecules \( b(\nu) \). This relation will be used to calculate the free energy of droplet formation.

A. Free energy of droplet formation \( W(\nu) \)

On the basis of nucleation thermodynamics, we know that if a liquid droplet is in mechanical and thermal equilibrium with the surrounding vapor, we have

\[ \partial W / \partial \nu = b(\nu) - b_1, \]

(67)

where \( W \) is the free energy of droplet formation in unit of \( k_B T \). Integrating Eq. (67) using the boundary condition \( W(0) = 0 \) (the formation free energy is zero for a bare solid particle) gives

\[ W(\nu) = \int_0^\nu d\nu (b(\nu) - b_1). \]

(68)

Note that our definition of \( \nu \) differs slightly from that in Ref. 2 by a value \( \nu_n \). The latter is the number of molecules of the liquid condensate required to fill the volume of solid particle. Because we consider liquid compressibility, \( \nu_n \) cannot be treated as a constant. Substituting \( d\nu \) [from Eq. (41)] into Eq. (68) gives

\[ W(\nu) = 4 \pi R_n^{(0)} \int_0^{\Gamma_{32}} b(\nu) d\Gamma_{31} + 4 \pi \int_{\Gamma_n}^{R_n} dR \rho_2 \sigma_{\infty}^2 b(R) \]

\[ \times \left[ 1 + x_2 k_B T \rho_2 \sigma_{\infty}^2 \left( \frac{R^3 - R_m^{(0)}}{3 R^2} \frac{db(R)}{dR} \right) \right] - b_1 \nu, \]

(69)

where \( b(R) \) is given by Eq. (39) and \( b(\nu) \) by Eq. (53). Again, keeping only the first-order terms of curvature and compressibility, we have

\[ W(\nu) = 4 \pi R_n^{(0)} \int_0^{\Gamma_{32}} b(\nu) d\Gamma_{31} + 4 \pi \int_{\Gamma_n}^{R_n} dR \rho_2 \sigma_{\infty}^2 b(R) \]

\[ \times \left[ 1 + x_2 k_B T \rho_2 \sigma_{\infty}^2 \left( \frac{R^3 - R_m^{(0)}}{3 R^2} \frac{db(R)}{dR} \right) \right] - b_1 \nu. \]

(69)

The two integrals involving \( d\Pi / dR \) can be further evaluated using the integration by parts, that is,

\[ 4 \pi x_2 \int_{\Gamma_n}^{R_n} R^2 \frac{d\Pi}{dR} \]

\[ = \frac{4 \pi}{3} x_2 \left( \frac{R^3 - R_n^{(0)}}{2 R_m^{(0)}} \right) \left( \frac{R}{2} \right)^2 \int_{\Gamma_n}^{R_n} R^2 \Pi^2 dR, \]

(71)

\[ - 4 \pi x_2 \int_{\Gamma_n}^{R_n} R^2 \frac{2 \sigma_{\infty}^2}{3 R^2} \frac{d\Pi}{dR} \]

\[ = - 4 \pi x_2 \sigma_{\infty}^2 \left( \frac{R^3 - R_n^{(0)}}{2 R_m^{(0)}} \right) \frac{R^2}{3} \int_{\Gamma_n}^{R_n} R^2 \Pi dR. \]

(72)

With Eq. (71), Eq. (70) becomes

\[ W(\nu) = 4 \pi R_n^{(0)} \int_0^{\Gamma_{32}} b(\nu) d\Gamma_{31} + 4 \pi \frac{R^3}{2 k_B T} \sigma_{\infty}^2 \left( \frac{1 - \frac{2 \delta_n}{R}}{R} \right) \]

\[ + \left( \frac{4 \pi}{3} \frac{R^3 - R_n^{(0)}}{R_m^{(0)}} x_2 \frac{2 \delta_n}{R} \right) \left( \frac{R^3}{2 k_B T} \sigma_{\infty}^2 \right) \left( \frac{1 - \frac{2 \delta_n}{R}}{R} \right) \]

\[ - \frac{4 \pi}{k_B T} \int_{\Gamma_n}^{R_n} R^2 \Pi dR - b_1 \nu. \]

(73)

This expression of \( W(\nu) \) can be reduced to the classical one \(^1\) if the first-order curvature and compressibility corrections are removed and if the adsorption term is included in II. Finally, we obtain the following expression for the free energy of droplet formation on the solid particle in the case of \( \nu > 4 \pi R_n^{(0)} \Gamma_{32} \):

\[ W(\nu) = 4 \pi R_n^{(0)} \left[ \Gamma_{32} \ln \left( \frac{\rho_2}{2} \right) \right] - 1 \]

\[ + \int_{\Gamma_n}^{\Gamma_{32}} K(\Gamma_{31}) d\Gamma_{31} + 4 \pi \frac{R^3}{2 k_B T} \sigma_{\infty}^2 \left( \frac{1 - \frac{2 \delta_n}{R}}{R} \right) \]

\[ + \left( \frac{4 \pi}{3} \frac{R^3 - R_n^{(0)}}{R_m^{(0)}} x_2 \frac{2 \delta_n}{R} \right) \left( \frac{R^3}{2 k_B T} \sigma_{\infty}^2 \right) \left( \frac{1 - \frac{2 \delta_n}{R}}{R} \right) \]

\[ - \frac{4 \pi}{k_B T} \int_{\Gamma_n}^{R_n} R^2 \Pi dR - b_1 \nu. \]

(73)

For \( \nu < 4 \pi R_n^{(0)} \Gamma_{32} \), we have
For the limiting case of $R_n = 0$ and $P = 0$, Eq. (73) will be reduced to

$$W_{\text{homog}}(n) = 4\pi R^2 n \left[ \Gamma_{31} \ln(a(R_n)\Gamma_{31}) - 1 \right]$$

$$+ \int_0^{\Gamma_{31}} \kappa(\Gamma_{31}) d\Gamma_{31} - b_1 n \nu.$$  \hspace{1cm} (74)

For the limiting case of $R_n = 0$ and $\Pi = 0$, Eq. (73) will be reduced to

$$W_{\text{homog}}(n) = 4\pi R^2 \sigma_{21}^\infty \left[ \frac{1}{k_B T} - \frac{2\delta_e}{R} \right]$$

$$+ \frac{4\pi}{3} R^3 \frac{\chi_2}{2k_B T} \left( \frac{2\sigma_{21}^\infty}{R} \right)^2 - b_1 n \nu,$$  \hspace{1cm} (75)

which indeed is the free energy of droplet formation for homogeneous nucleation. Therefore, the difference $W(n) - W_{\text{homog}}(n)$ can be identified as the work of wetting, which is entirely due to the presence of the solid particle.

To calculate the integrals in Eq. (73) we used numerical results for $P(h)$ up to a certain value of $R$, and beyond that $R$ we used the power-law approximation [Eq. (29)]. Results of $W(n)$ for given $b_1$ and $R_n$ are shown in Fig. 7. All the $W(n)$ curves exhibit the "loop" behavior which is typical for heterogeneous nucleation. Similar behavior has been predicted from the classical theory, but only qualitatively because the theory utilizes numerous empirical parameters. The minimum on these curves corresponds to the equilibrium size $n_e$, at which the solid particle is covered by a liquid film with a finite thickness and in stable equilibrium with the surrounding supersaturated vapor. The value $W_e = W(n_e)$ is negative, which means the formation of the equilibrium liquid film is spontaneous but it cannot grow further into a liquid droplet. The maximum at $n_c$ on the $W(n)$ curves corresponds to the peak of the barrier.

### B. The barrier height to nucleation $\Delta W$

The height of the barrier is defined as $\Delta W = W(n_c) - W(n_e)$. Typically, $\Delta W$ is no greater than several tens of $k_B T$ for which the nucleation rate is measurable. If $n > n_c$, the size of the droplet is large enough to overcome the barrier to nucleation. As $b_1 \to b_1^\text{th}$ from below, both $n_c$ and $n_e$ approach $n_m$. As we know, $n_m$ depends on $R_n$ but not on the supersaturation characterized by $b_1$. This means that whenever $b_1 = b_1^\text{th}$, $\Delta W(n_m) = 0$, that is, the nucleation becomes barrierless.
As discussed in Sec. IV, we are particularly interested in the near-threshold region, where the nucleation barrier is less than a few tens of $k_B T$ (see Fig. 7). It has been shown in Ref. 2 that in the near-threshold region the parabolic approximation [Eq. (56)] to $b(\nu)$ is valid, and thus Eq. (68) becomes

$$\Delta W = \int_{\nu_c}^{\nu_e} d\nu (b(\nu) - b)$$

$$= \frac{4}{3} e^{3/2} b^3 m^2 \left[ \frac{2}{d^2 b(\nu)/d\nu^2} \right]^{1/2}.$$  \hspace{1cm} (76)

Moreover, in the region near $\nu_c$ and $\nu_e$ one has

$$W = W_c - \left( \frac{\nu - \nu_c}{\Delta \nu_c} \right)^2, \quad W = W_c - \left( \frac{\nu - \nu_c}{\Delta \nu_c} \right)^2,$$  \hspace{1cm} (77)

where $\Delta \nu_c$ and $\Delta \nu_e$ are the half width of the minimum and maximum on the $W(\nu)$ curve, respectively, and are given by

$$\Delta \nu_c = \frac{2}{e b_{21} d^2 b(\nu)/d\nu^2} \left( \frac{1}{m} \right)^{1/4}.$$  \hspace{1cm} (78)

Using $b_{21}$ [Eq. (66)] and $|d^2 b(\nu)/d\nu^2|_{\nu_m}$ [Eq. (C2)] obtained in this work and substituting them into Eq. (76), keeping only first-order terms of curvature and compressibility, gives

$$\Delta W = \frac{8}{3} e^{3/2} \frac{1}{k_B T} 4 \pi R_m^{(0)2} \sigma_{21} \frac{R_m^{(0)} + \tilde{R}_n}{3 R_m^{(0)} + \tilde{R}_n} \left( \frac{R_m^{(0)} - \tilde{R}_n}{(R_m^{(0)} + \tilde{R}_n)^{1/2}} \right) \times$$

$$\left[ 1 + \frac{\delta_{21} 19 R_m^{(0)} + 26 R_m^{(0)2} \tilde{R}_n + 3 R_m^{(0)} \tilde{R}_n^2 - 4 R_n^{(0)}}{4 (2 R_m^{(0)} + \tilde{R}_n)^2} \sigma_{21} \chi_2 \frac{28 R_m^{(0)} + 56 R_m^{(0)2} \tilde{R}_n + 35 R_m^{(0)} \tilde{R}_n^2 + 7 \tilde{R}_n^3}{3 (2 R_m^{(0)} + \tilde{R}_n)^2} \right].$$  \hspace{1cm} (79)

In Fig. 8 we plot $\Delta W$ as a function of parameter $\epsilon$ for given $R_n$. Two sets of curves can be seen in Fig. 8. The first is obtained by using $\Delta W = W(\nu_e) - W(\nu_c)$ with the numerical results shown in Fig. 7. The second is obtained by using Eq. (79) with $\epsilon \leq 0.08$ (in the near-threshold region). The fact that both sets of curves show very good agreement indicates Eq. (79) indeed gives quite accurate prediction on the barrier height in the near-threshold region. Furthermore, if the curvature and compressibility corrections are neglected [in Eq. (79)] and if Eq. (79) is expanded over the small thickness of the film, $R_m^{(0)} - \tilde{R}_n$, the classical formula (7.16) in Ref. 2 will be reproduced. This result shows that our approach can recover not only results of the classical theory, but also evaluate the extent to which those approximations underlying the classical theory are applicable.

The half-width $\Delta \nu_c$ and $\Delta \nu_e$ can be calculated for our model via combining Eqs. (66) and (C2) with Eq. (78), which gives

$$\Delta \nu_c = \frac{\rho_{21} R_m^{(0)2} \sigma_{21} \chi_2}{(2 \pi k_B T)^{1/4}} \left( \frac{3 R_m^{(0)} + \tilde{R}_n}{2 R_m^{(0)} + \tilde{R}_n} \right)^{1/4} \times$$

$$\left[ 1 + \frac{\delta_{21} 19 R_m^{(0)} + 26 R_m^{(0)2} \tilde{R}_n + 3 R_m^{(0)} \tilde{R}_n^2 - 4 R_n^{(0)}}{4 (2 R_m^{(0)} + \tilde{R}_n)^2} \sigma_{21} \chi_2 \frac{28 R_m^{(0)} + 56 R_m^{(0)2} \tilde{R}_n + 35 R_m^{(0)} \tilde{R}_n^2 + 7 \tilde{R}_n^3}{3 (2 R_m^{(0)} + \tilde{R}_n)^2} \right].$$  \hspace{1cm} (80)

Figure 9 shows the calculated $\Delta \nu_c$ and $\Delta \nu_e$ as a function of $\epsilon$ parameter for given $R_n$ and temperatures. The magnitude of $\Delta \nu_c$ and $\Delta \nu_e$ is important to the kinetics of heterogeneous nucleation. On one hand, we notice from Fig. 9 that

$$\Delta \nu_c \gg 1, \quad \Delta \nu_e \gg 1,$$  \hspace{1cm} (81)

for given $\epsilon$ in the near-threshold region. This condition has been invoked in the classical theory because it allows the number of particles to be used as a continuous variable.
The classical approach is that the hybrid approach takes into account the first-order curvature and compressibility corrections. Such corrections cannot be given in the classical theory because parameters such as the compressibility and the Tolman length cannot be known without employing certain models for the microscopic structure of the liquid. The use of DFT allows us to find these important characteristics of the fluid, which are neglected or treated with empirical parameters in the classical theory.

Our results (Fig. 2) show that the disjoining pressure \( \Pi(h) \) of the LJ liquid film near the solid surface is a monotonic function of the film’s thickness \( h \). We have confirmed several approximations to \( \Pi(h) \) used in the classical nucleation theory.\(^2\) These include the power-law approximation for thick films and the exponential approximation for thin films. Several key constants involved in these approximations, such as the Hamaker constant and the correlation length in the exponential approximation, have been evaluated directly from the DFT. In the classical theory, however, those constants were not known. That theory could only estimate them based on either experiments or other microscopic theories.

In this study we consider heterogeneous nucleation on mesoscopic wettable particles. Because of the mesoscopic size, only the first-order corrections due to the curvature (the Tolman length) and compressibility have been taken into account. Again, these corrections can be obtained in the framework of DFT but not from the classical approach. The classical approach becomes more valid when the solid particle is beyond mesoscopic, for which those first-order corrections can be neglected entirely.

We have investigated the temperature dependencies of the surface tension and the Tolman length of the liquid–vapor interface by using a nonlocal WDA-DFT. To our knowledge, this is the first study of the Tolman length using WDA-DFT. We find the WDA gives qualitatively similar results of surface tension and the Tolman length as LDA. In particular, the WDA-DFT predicts a negative sign of \( \delta_{\alpha} \), as does the LDA-DFT. This result is useful not only for this study, but also for other problems involving surfaces of large droplets.

Another main result of this work is the dependence of the chemical potential of liquid condensate on the size of the droplet \( b(R) \) or the number of molecules \( b(v) \). We find that the chemical potential is a nonmonotonic function of \( R \) or \( v \). A maximum appears on the \( b(R) \) or \( b(v) \) curve, which gives rise to a threshold value of the chemical potential \( b_{th} \) at \( R_m \) or \( v_m \). When the chemical potential of the vapor \( b \) is greater than \( b_{th} \), the nucleation process becomes barrierless. We also find that for large solid particles, \( R_m \) is always in the region of thick films for which the power-law approximation to \( II \) is applicable. This fact was not obvious in the classical theory because of the lack of exact calculation of \( R_m \). The power-law approximation has been used to obtain analytical expressions for some nucleation characteristics. Wherever the power-law approximation is applicable, e.g., for nonpolar fluids on large wettable solid particle, we find that our analytical expressions can be reduced to the classical ones\(^2\) by neglecting curvature and compressibility corrections. Even with the ne-
The steady-state rate of nucleation is given by

\[ \dot{n}^{(n)}(\nu) = \frac{n_n}{\pi^{3/2} \Delta \nu_e} \exp(-\Delta W) \exp\left[\frac{(\nu - \nu_e)^2}{2 \Delta \nu_e}\right], \]

where \( n_n \) is the number of solid particles per unit volume, as well as the steady-state distribution in the near-threshold region

\[ \dot{n}^{(n)}(\nu) = \frac{n_n \exp(-\Delta W)}{\pi^{3/2} \Delta \nu_e \Delta \nu_c} \exp\left[\frac{(\nu - \nu_e)^2}{2 \Delta \nu_e}\right] \times \int_{\nu - \Delta \nu_c}^{\nu + \Delta \nu_c} d\nu' \exp\left[\frac{(-\nu' - \nu_e)^2}{2 \Delta \nu_e}\right]. \]

The steady-state rate of nucleation is given by

\[ j^{(n)} = \frac{n_n \nu_0}{\pi \Delta \nu_e \Delta \nu_c} \exp(-\Delta W), \]

where \( \nu_0 \) is the number of molecules attached to the surface of the droplet (with size \( R_m \)) per unit time at the so-called free-molecule regime. Our calculation of \( R_m, \nu_m, \nu_e, \nu_c \), and that shown in Figs. 8 and 9 all can be used in these formulas to investigate the kinetics of heterogeneous nucleation on mesoscopic solid particles.

**APPENDIX A: EVALUATION OF SURFACE TENSION AND THE TOLMAN LENGTH USING WDA-DFT**

The surface tension and the Tolman length can be evaluated from either molecular simulations or DFT. For small \( R \), both DFT and molecular simulations predict a positive sign of the Tolman length \( \delta(R) \). However, the sign of \( \delta_n \) (for \( R \to \infty \)) is still controversial due to the lack of experimental measurements. One molecular dynamics simulation predicted that the Tolman length is negative, whereas another predicted that it is positive. Thus far, all DFT has suggested that \( \delta_n \) is a small negative quantity.

The question is to what extent the underlying approximations in DFT, such as the random-phase approximation (RPA) or the local density approximation (LDA), affect the predicted outcome. Could the negative sign of \( \delta_n \) be an artifact of some approximations? In a previous study, we examined the effects of the RPA and an improved modified mean-field approximation (MMFA) in the framework of LDA-DFT. That study showed that the MMFA leads to a slight decrease of \( |\delta_n| \) but still predicts a negative sign of \( \delta_n \). Here, we examine effects of WDA on \( \delta_n \). To our knowledge, this is the first calculation of \( \delta_n \) based on the nonlocal WDA-DFT. Results will be compared with those based on LDA-DFT.

We calculate \( \sigma_{21} \) and \( \delta_n \) by using the statistical-mechanics formulas derived by Blokhuis and Bedeaux, which are applicable to systems with pairwise intermolecular potential. A key input for these formulas is the density profile of the planar liquid–vapor interface \( \rho(z) \). It turns out that \( \delta_n \) is strongly dependent on the symmetry of the density profile. For example, if one uses the symmetric hyperbolic-tangent density profile resulting from the gradient-expansion DFT, \( \delta_n = 0 \). It is known that WDA can lead to microscopic oscillation on \( \rho(z) \) at the liquid side at low temperatures and high liquid densities (above the so-called Fisk–Widom line). In other words, the WDA can significantly change the symmetry of the density profile. It is of interest to see how this oscillation behavior in \( \rho(z) \) affects \( \delta_n \).

We notice that the original Blokhuis–Bedeaux formulas cannot be directly applied here due to the nonlocal nature of the WDA. Generalization of these formulas can be made by replacing the pairwise potential \( w_p(r_{12}) \) with the effective pairwise potential \( w_p(r_{12}) + \phi_{hs}(r_{12}, \rho(r_2)) \), where

\[ \phi_{hs} = \frac{2 \Delta \psi_{hs}(\rho)}{1 - \rho_1 - 2 \rho \rho_2}. \]

Indeed, in order to calculate the surface tension and the Tolman length, one has to find the variation of the system’s free energy under different coordinate transformation, but keep the volume of the system unchanged. As was shown in our previous work, the only part of the free energy which contributes to this variation is the nonlocal part, that is, according to Eq. (15)

\[ F_{\text{nonlocal}}[\rho] = \int d\mathbf{r}_2 \rho(\mathbf{r}_2) \Delta \psi_{hs}(\rho(\mathbf{r}_2)) + \frac{1}{2} \int \int d\mathbf{r}_1 d\mathbf{r}_2 w_p(r_{12}) \rho(\mathbf{r}_1) \rho(\mathbf{r}_2). \]
\[ \delta F_{\text{nonlocal}}[\rho] = \int dr_2 \rho(z_2) \Delta \psi_{h_2}(\rho(z_2)) \delta \rho(z_2) \]
\[ + \frac{1}{2} \int dr_1 \int dr_2 \delta \omega_p(r_{12}) \rho(z_1) \rho(z_2). \]  

(A3)

Taking into account Eq. (16), after some mathematical work the variation becomes
\[ \delta F_{\text{nonlocal}}[\rho] = \int dr_1 \int dr_2 \rho(z_2) \delta \omega_p'(r_{12}) \Delta \psi_{h_2}(\rho(z_2)) \]
\[ \times \left( 1 - \hat{\rho}(z_2) - 2 \hat{\rho}(z_2) \bar{\rho}(z_2) \right) \]
\[ + \frac{1}{2} \delta \omega_p(r_{12}) \delta \rho(z_2), \]  

(A4)

where \( \mathbf{e} \) is the unit vector in the direction of \( \mathbf{r}_{12} \). The variation becomes the same as Eq. (8) in Ref. 37 by replacing the potential \( w_p(r_{12}) \) there with the effective pairwise potential \( w_p'(r_{12}) + \phi_{h_2} \omega(r_{12}, \bar{\rho}(\mathbf{r}_2)) \). The rest of the derivation of the surface tension and the Tolman length will then follow that in Ref. 37.

Thus, the generalized formula for the surface tension is
\[ \sigma^{\infty}_{21} = \frac{\pi}{2} \int dz_1 \int r_{12}^2 dr_{12} \int_1^1 ds \left[ \frac{\partial \omega_p'(r_{12})}{\partial r_{12}} \right. \]
\[ + \phi_{h_2}(z_1 + sr_{12}) \left. \frac{\partial \omega(r_{12}, \bar{\rho}(z_1 + sr_{12}))}{\partial r_{12}} \right] r_{12}(1 - 3s^2) \]
\[ \times \rho(z_1) \rho(z_1 + sr_{12}). \]  

(A5)

This formula differs from the original one by having the second term in the square bracket, due to the nonlocal functional Eq. (A1). Using the integration by parts, Eq. (A5) can be written in a similar form as in Ref. 34, that is
\[ \sigma^{\infty}_{21} = \pi \int dz_1 \int r_{12}^2 dr_{12} \int_1^1 ds \left[ \frac{\partial \omega'(r_{12})}{\partial r_{12}} \right. \]
\[ + \phi_{h_2}(z_1 + sr_{12}) \left. \frac{\partial \omega(r_{12}, \bar{\rho}(z_1 + sr_{12}))}{\partial r_{12}} \right] r_{12} \frac{1}{2} \left( 1 - 3s^2 \right) \]
\[ \times \rho(z_1) \rho(z_1 + sr_{12}). \]  

(A6)

The generalized formula Eq. (A5) or (A6) allows us to evaluate \( \sigma^{\infty}_{21} \) by using the density profile calculated from the WDA-DFT. Results of \( \sigma^{\infty}_{21} \) at various temperatures are shown in Fig. 10, as well as those \( \sigma^{\infty}_{21} \) calculated from the LDA-DFT using the original formulas. \( \overset{28}{34} \) Generally, the WDA gives a lower \( \sigma^{\infty}_{21} \) than the LDA. The difference is bigger at low temperatures above the Fisk–Widom line, where the density profile exhibits oscillatory behavior. But, the difference is still less than 7%. Previously, we showed \( \overset{27}{37} \) that the difference in \( \sigma^{\infty}_{21} \) by replacing the RPA with the MMFA amounts to 20% at the low temperatures.

The generalized statistical-mechanics formula for the Tolman length is
\[ \delta_\infty = -\frac{\pi}{4\sigma^{\infty}_{21}} \int dz_1 \int r_{12}^2 dr_{12} \int_1^1 ds \left[ \frac{\partial w_p'(r_{12})}{\partial r_{12}} \right. \]
\[ + \phi_{h_2}(z_1 + sr_{12}) \left. \frac{\partial \omega(r_{12}, \bar{\rho}(z_1 + sr_{12}))}{\partial r_{12}} \right] r_{12}(1 - 3s^2) \]
\[ \times (2z_1 + sr_{12}) \rho(z_1)(z_1 + sr_{12}). \]  

(A7)

As in the original Blokhuis–Bedeaux formula, a condition for applying Eq. (A7) is that the density profile should be calculated using the equilibrium dividing surface. Otherwise, additional terms must be included. Again, using the integration by parts, Eq. (A7) can be written in a similar way as Eq. (A6), that is,
\[ \delta_\infty = -\frac{\pi}{2\sigma^{\infty}_{21}} \int dz_1 \int r_{12}^2 dr_{12} \int_1^1 ds \left[ \frac{\partial \omega'(r_{12})}{\partial r_{12}} \right. \]
\[ + \phi_{h_2}(z_1 + sr_{12}) \left. \frac{\partial \omega(r_{12}, \bar{\rho}(z_1 + sr_{12}))}{\partial r_{12}} \right] \rho(z_1) \rho(z_1 + sr_{12}) \frac{1}{2} \left( 1 - 3s^2 \right) \]
\[ \times (2z_1 + sr_{12}) \rho(z_1). \]  

(A8)

The calculated \( \delta_\infty \) at various temperatures is shown in Fig. 11, along with that from the LDA-DFT. Interestingly, we find that the sign of \( \delta_\infty \) predicted by using WDA-DFT is still negative, that is, the nonlocal DFT does not qualitatively change the sign of \( \delta_\infty \). This conclusion is an important by-product of this work.

**APPENDIX B: CALCULATION OF THE CONSTANT \( c(\bar{R}_n) \)**

We follow the method introduced in Ref. 5 to derive \( c(\bar{R}_n) \) by using a patching condition \( db(v)/dv|_{\Gamma_{31} = \Gamma_{32}} = db(v)/dv|_{\bar{R}_n} \). First, we have from Eq. (41) that
\[ \lim_{\bar{R} \to \bar{R}_n} \frac{db(v)}{dv} = \frac{1}{4\pi R^2_0 \rho_{2n}(1 + 2\rho_{2n} \chi_{2n} T b(v))} \frac{db(R)}{dR} \]  

(B1)

Next, using the patching condition and Eq. (B1), we have
Finally, substituting Eq. (52) to the left-hand side of (B2) and Eq. (39) to the right-hand side of (B2), and keeping only the first-order terms of curvature and compressibility gives a linear equation for $c(R_n)$, that is

$$d b(v) \big|_{\Gamma_{31} - \Gamma_{32}} = \frac{1}{\rho_{2\perp} k_B T} \frac{d b(R)}{d R} \bigg|_{R=R_n}.$$

(B2)

The third derivative can be expressed as

$$[d^3 b(v)/d v^3]_{R_n} = - \left[ 3/D(R)^3 \right] [d D(R)/d R] [d^2 b(R)/d R^2]_{R_n} + \left[ 1/D(R)^3 \right] [d^3 b(R)/d R^3]_{R_n},$$

where we also used $[d b(R)/d R]_{R_n=0} = 0$. Using Eqs. (29), (39), (60), (61), and (67), we obtain

$$d^3 b(v) \bigg|_{v_n} = \frac{1}{d v^3} d^3 b(R) \bigg|_{R_n} = \frac{1}{D(R)^2} \frac{1}{d R^2} \bigg|_{R_n}$$

$$= \frac{4 \sigma_{21}^2}{4 \pi^2 \rho_{2\perp}^2 k_B T R_m^{102}} \left[ R_m^{102} + 6 R_m^{102} R_n - 9 R_n^2 \right]$$

$$\times \left( R_m^{100} - R_n^2 \right)^2,$$

where we just include the leading order of $R_m^{102}$ without considering the curvature and compressibility corrections. This is sufficient to give a reasonable estimation of the $\rho$ parameter via Eq. (59), that is,

$$\frac{1}{3} \varepsilon^{1/2} \left( \frac{2 R_m^{100} + R_n^2}{3 R_m^{100}} \right)^{1/2} \left[ 13 R_m^{100} + 6 R_m^{102} R_n - 9 R_n^2 \right]$$

$$\times \left( R_m^{100} - R_n^2 \right)^{1/2} \left( R_m^{102} - R_n^2 \right)^{1/2} \left( R_m^{102} + R_n^2 \right) \approx 1.$$  

(C3)

Using the above equation with Eq. (63), we find that the validity of the parabolic approximation requires $\varepsilon < 0.08$ for $5d < R_n < 20d$. For larger $R_n$, $\varepsilon$ should be even smaller.
