Abstract—Employing waveband switching (WBS) in WDM networks can reduce the network operational cost and the call blocking probability. However, upgrading the existing optical switching architecture requires time and money. It is expected that a heterogeneous waveband switching (HeteroWBS) architecture would be desirable, where some nodes can support WBS functions and some cannot. We study the performance of HeteroWBS networks in terms of call blocking probability and cost savings under dynamic traffic requests. We propose an autonomous clustering-based HeteroWBS (AS-HeteroWBS) architecture to clusters the network into multiple autonomous systems (ASs). An AS may contain some specific nodes that provide WBS functions for all the nodes in the AS. Based on the architecture, three HeteroWBS algorithms are proposed. Our simulation results show that the HeteroWBS algorithms can achieve optimal cost savings while maintaining the same network throughput compared with the algorithm without WBS.

I. INTRODUCTION

Wavelength division multiplexing (WDM) is an important technique for the next-generation networks [1], [2]. As the number of wavelengths in a fiber increases, the WDM network provisioning and management functions become more complex and the number of optical components increases. Waveband switching (WBS) has been proposed as an efficient solution in [3]–[5] to solve those problems.

Through WBS, a small set of wavelengths is aggregated into a waveband (wavelength band) at an optical cross-connect (OXC), transmitted as a whole along fiber links, and disaggregated back into wavelengths at another OXC. A waveband-route, formed along those fiber links and OXCs, can reduce the number of utilized OXC ports compared with the corresponding wavelength-routes (lightpaths) [6]. Thus, adopting WBS can generate more revenue by minimizing the switching and transmission costs in the optical domain of WDM networks, which are dominated by the number of OXC ports used. Other advantages can also be achieved, such as reducing the OXC size and complexity [7].

By adding a waveband crossconnect fabric and adopting mixed band (de)multiplexers, an OXC is capable of waveband switching, which is denoted as band-switching optical cross-connect (BOXC). By adding waveband (de)multiplexers, a BOXC can group and disaggregate wavebands, which is denoted as a multi-granular optical cross-connect (MGOXC) and is shown in Fig. 1. An MGOXC can also adopt (de)multiplexers that (de)multiplex wavebands from a fiber first and then (de)multiplex wavelengths from wavebands. Such an MGOXC is illustrated in [3], [5].

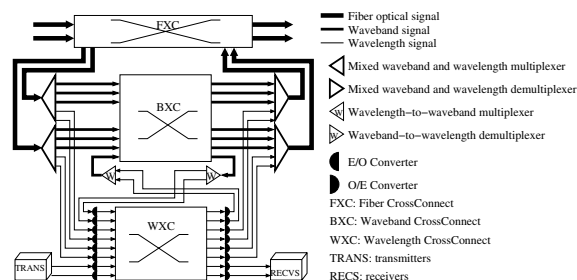

Fig. 1. An illustration of a multi-granular optical cross-connect (MGOXC) capable of mixed waveband/wavelength switching, wavebands grouping, and wavebands disaggregating.

A WDM network with the functionality of WBS is a waveband-switching network (WBS network). However, upgrading the existing optical switching architecture requires time and money. It is expected that a heterogeneous waveband switching (HeteroWBS) architecture would be desirable, where some nodes can support WBS functions and some cannot. As the blocked calls influence the network throughput, it is important to study the performance of HeteroWBS networks in terms of call blocking probability and cost savings.

In a HeteroWBS network, dynamically arriving traffic should be provisioned through either wavelength-routes or waveband-routes. We analyze the HeteroWBS network architecture and cluster the whole network into multiple autonomous systems (ASs). Based on the autonomous clustering architecture, three HeteroWBS algorithms adopting different routing algorithms are proposed. Substantial simulations are conducted to study the network performance. Our simulation results show that the HeteroWBS algorithms can achieve optimal performance compared with the algorithm without waveband switching.

The rest of the paper is organized as follows. Section II defines the dynamic HeteroWBS problem in detail. Section III describes the autonomous clustering-based HeteroWBS architecture. Section IV presents the three algorithms based on the architecture. The simulation results are illustrated in Section V. Finally, Section VI concludes the paper.

II. NETWORK CONFIGURATION AND PROBLEM STATEMENT

A. Network Node Architecture

We consider the mixed waveband-wavelength switching, where the (de)multiplexing of wavebands and wavelengths

from a fiber is completed at the same time by adopting band (de)multiplexers. Fig. 1 presents the architecture of such an MGOXC. An MGOXC may support two types of waveband switching, namely the uniform waveband switching (UWBS) and the non-uniform waveband switching (NUWBS). In both types of waveband switchings, the waveband granularity is an important factor in achieving maximum cost savings [5], [8]. In this paper, we consider UWBS.

B. Network Configuration

In a HeteroWBS network, there are two types of network nodes. Some are MGOXCs supporting WBS functions. The others are ordinary OXCs. The network can be divided into two hierarchies, namely the wavelength crossconnecting (WXC) layer and the waveband crossconnecting (BXC) layer. Establishing and tearing down connections may involve nodes of both types through both layers.

Let the mesh network consist of N nodes and J unidirectional links. Each node is a routing node with an MGOXC or an OXC. Each link is a fiber link carrying W wavelengths. It may also carry B wavebands, each of which may consist of at most G specific wavelengths. G is also referred to as the waveband granularity. For a HeteroWBS network supporting mixed waveband-wavelength switching, only a fraction of wavelengths are grouped in wavebands. Therefore, a fiber link may contain both active wavelengths and active wavebands and $B \times G \leq W$. We define a ratio $r = \frac{B \times G}{W}$, where $0 \leq r \leq 1$. r is the ratio of the number of wavelengths in wavebands to the total number of wavelengths in a fiber. In addition, depending on the utilized MGOXCs, the set of wavelengths in a waveband is specified beforehand. For example, a waveband b_i may consist of G contiguous wavelengths $w_{(i-1)G}, w_{(i-1)G+1}, \dots, w_{iG-1}$.

C. Problem Statement and Connection Management

In a HeteroWBS network, a dynamically arriving call should be provisioned either along a wavelength-route or along an intermediate/end-to-end waveband-route [9]. The problem of provisioning a call in a HeteroWBS network can be divided into searching for a candidate path, referred to as *routing*, searching for a free wavelength with or without waveband grouping requirements, referred to as *wavelength assignment*, and searching for an available waveband along the sub-paths of the candidate path, referred to as *waveband assignment*. The whole problem is then called routing, wavelength and waveband assignment (RWWBA) problem. To focus on adopting the WBS technique in a HeteroWBS network, it is assumed that each call requires a whole wavelength capacity. We also conducted simulations in networks, where each call may require more than one wavelength. The results are similar.

A connection in a HeteroWBS network may be originated from and terminated at either an OXC or an MGOXC. To accommodate the connection, a waveband-route may be set up or adopted along a sub-path. All the nodes along the waveband-route should be MGOXC nodes. As a waveband-route should be at least two hops to be cost-efficient [4], the

path for a connection through multiple intermediate waveband-routes has at least four hops. In addition, the available wavelengths are restricted to those in the waveband along all the waveband-routes and along the remaining wavelength-routes. Moreover, provisioning connections through multiple intermediate waveband-routes may increase the path length unnecessarily. This may waste the network resources, which in turn increases the call blocking probability and degrades the network performance. Thus, a connection is allowed to be routed through at most one intermediate waveband-route.

III. AUTONOMOUS CLUSTERING-BASED HETEROGENEOUS WAVEBAND-SWITCHING ARCHITECTURE

To manage the connections, the HeteroWBS network is clustered into multiple autonomous systems (ASs) ruled by the grouping strategy. The most prominent characteristic of an AS is that the WBS managements are controlled only by the MGOXC nodes in the AS. This section first presents an efficient autonomous connection management, which can conceal the WBS information from the ordinary OXC nodes. To support the efficient autonomous connection management, an autonomous clustering-based heterogeneous waveband switching (AS-HeteroWBS) architecture is then proposed.

A. Autonomous Connection Management

When a connection request is initiated by the end-users or the upper layer applications, the source node searches for an available path. In doing so, the nodes communicate with each other about their current configurations. As MGOXC nodes are responsible for managing waveband switching, the information about the waveband availability and the wavelength availability in the wavebands should be shared among the MGOXC nodes. However, the type of information is not necessary for the ordinary OXC nodes. The communication among the ordinary OXC nodes for the type of information is not necessary. Thus, we introduce autonomous connection management to discover the current network configurations while screening the WBS information from the ordinary OXC nodes.

It is important to point out that the MGOXC nodes should be connected with other MGOXC nodes to take advantage of WBS. Initially, an MGOXC node does not know which of its neighbors are MGOXC nodes. An initial BXC message should be distributed. If its ordinary OXC neighbor receives this message, it simply discards it. Otherwise, upon receiving the message, the neighbor MGOXC node should response with its available wavebands and available wavelengths in the wavebands. Additionally, to discover the initial network configuration, all MGOXCs and ordinary OXCs distribute an initial WXC message and confirm the presence of their neighbors with their available wavelengths upon the receipt of the message.

A connection originating from an ordinary OXC may go through a waveband-route. However, the source node has no information about the current available wavebands. It should

communicate with one of the MGOXCs in the network. Moreover, if the MGOXC is along the waveband-route, it would eliminate the waveband-route information and just advise the source node with the available wavelengths in wavebands. Through this method, the waveband switching is transparent to the ordinary OXCs. Based on the idea, we propose an autonomous clustering-based HeteroWBS architecture in the following subsection.

B. Autonomous Clustering-Based Heterogeneous WBS Architecture

An autonomous clustering-based heterogeneous waveband switching (AS-HeteroWBS) optical network architecture is proposed to make WBS transparent to the ordinary OXCs. The clustering of the network is ruled by the grouping strategy. First, the grouping strategy attaches MGOXCs to ordinary OXCs in the network. Given a HeteroWBS network with a set of connected MGOXCs, an ordinary OXC n_c selects its attached MGOXCs according to the following.

- If n_c has neighbor MGOXCs, it adds all the neighbor MGOXCs as its attached MGOXCs. Otherwise, continue.
- If n_c can reach multiple MGOXCs that are two-hops away, it picks the one with the smallest distance as its attached MGOXC. Otherwise, continue.
- If n_c can reach MGOXCs through at least three hops, it will not be assigned with any attached MGOXC. In other words, the connection originating from n_c will always be accommodated through a lightpath.

The rationale of assigning an attached MGOXC that is one-hop or two-hops away to an OXC is to adopt WBS for a connection with maximum possibility. Moreover, by not attaching MGOXCs that are at least three-hops away from the OXC node, we can reduce the possibility of wasting network resources in routing connections through long paths along intermediate waveband-routes.

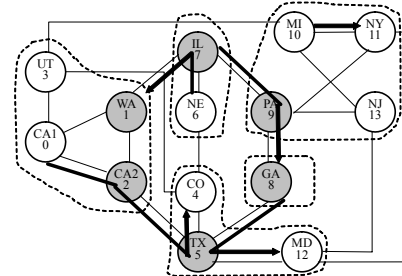

After determining the attached MGOXC(s) for each ordinary OXC, the ASs can be determined as follows.

- If the ordinary OXC nodes $n_{i1}, ..n_{ij}$ have the same attached MGOXC node b_k and b_k is the only attached MGOXC for all of them, the ordinary nodes $n_{i1}, ..n_{ij}$ and the MGOXC b_k are clustered into an AS $\{n_{i1}, ..n_{ij}, b_k\}$.
- Assume that an ordinary OXC node n_i has only one attached MGOXC b_{j1} and b_{j1} is one of the attached MGOXC in an AS $\{n_{k1}, .., n_{kx}, b_{j1}, .., b_{jy}\}$. If n_i is at most two-hops away from all of the attached MGOXCs $b_{j1}, .., b_{jy}$ in the AS, add n_i into the AS. Otherwise, n_i and b_{j1} are clustered into a separate AS.
- If there is no attached MGOXC for an ordinary OXC n_i , it is clustered into a separate AS, which contains node n_i only.

The clustering process continues until there is no change for all the ASs in the network. The rationale of enlarging the ASs is to encourage the adoption of lightpaths with only one or two hops.

(a) The heterogeneous NSF network, where gray nodes are MGOXC nodes and white nodes are ordinary OXC nodes

(b) The clustering NSF network. The dash circle delimitates the cluster and the gray nodes are the group nodes in the cluster.

Fig. 2. An illustration of clustering the nodes in a heterogeneous waveband switching network.

An illustration of clustering the HeteroWBS network into ASs is shown in Fig. 2. The example NSF network is a HeteroWBS network with six MGOXC nodes, which are WA_1 , CA_{22} , TX_5 , IL_7 , GA_8 , and PA_9 . The ordinary OXC node UT_3 can reach three MGOXCs through two-hops routes. The three MGOXCs are WA_1 , CA_{22} , and TX_5 . Node UT_3 selects MGOXC WA_1 as its attached node since the path from UT_3 to WA_1 is the shortest. Initially, node CA_{10} selects all the neighbor MGOXCs CA_{22} and WA_1 as its attached MGOXCs. Since UT_3 is only two-hops away from CA_{22} , the clustering process adds UT_3 into the AS $\{CA_{10}, CA_{22}, WA_1\}$. The other ASs can be derived through the same process and are shown in Fig. 2. If the OXC has no attached MGOXC, it by itself forms an AS. The MGOXC nodes in the ASs are called the group nodes.

IV. HETEROGENEOUS WAVEBAND SWITCHING ALGORITHM DESIGN

Three HeteroWBS algorithms are proposed based on the AS-HeteroWBS architecture to solve the dynamic RWWBA problem. The algorithms adopt first-fit waveband assignment and first-fit wavelength assignment. We focus on the HeteroWBS algorithm design with different routing algorithms.

The HeteroWBS algorithms provision a connection request $c(s, d)$ upon its arrival dynamically. $c(s, d)$ can be one of the following eight classes in the AS-HeteroWBS network.

- [C1] s and d are within the same AS, where s and d are both MGOXCs.
- [C2] s and d are within the same AS, where s is an MGOXC and d is an ordinary OXC.

- [C3] s and d are within the same AS, where s is an ordinary OXC and d is an MGOXC.
- [C4] s and d are within the same AS, where s and d are both ordinary OXCs.
- [C5] s is in different AS from d , where s and d are both MGOXCs.
- [C6] s is in different AS from d , where s is an MGOXC and d is an ordinary OXC.
- [C7] s is in different AS from d , where s is an ordinary OXC and d is an MGOXC.
- [C8] s is in different AS from d , where s and d are both ordinary OXCs.

A. Autonomous Heterogeneous Waveband Switching (AS-WBS) Algorithm

Now the network nodes have been clustered into multiple ASs. The MGOXCs comprise the BXC layer in the AS-HeteroWBS network. We propose the AS-WBS algorithm to manage BXC only at the group nodes of each ASs. The AS-WBS algorithm accommodates connections according to the following three principles.

- A waveband-path is more preferable than a lightpath.
- A lightpath (L_i) across ASs for a connection is preferred if the other paths are at least two hops longer than L_i . For example, if a connection request $c(UT_3, CO_4)$ arrives, the lightpath across ASs along route $UT_3 \rightarrow CO_4$ is preferred as shown in Fig. 2(b).
- The path with the smallest hop count within an AS is preferred.

We describe the AS-WBS algorithm for a connection request $c(s, d)$ one class at a time as follows.

- I. $c(s, d)$ is in class C1 or C5:
 - if there is an active waveband-path $B(s, d)$ from s to d with available wavelengths, c is grouped into B .
 - Otherwise, if a new waveband-path $B_w(s, d)$ from s to d along the shortest path can be set up, c is routed through B_w .
 - Otherwise, if a new lightpath λ_c along the shortest path can be set up, c is routed through λ_c .
 - Otherwise, adopt the k-shortest path algorithm and search for any available path.
 - If no path is available, c is blocked.
- II. $c(s, d)$ is in class C2, C3, or C4:
 - Recall that a path within the AS is preferred to the one across the AS if the path is short. Thus, AS-WBS searches for an available shortest path within the cluster and sets up a new lightpath if the path is only one or two hops long. Otherwise, continue.
 - Adopt the k-shortest path algorithm and search for any available path.
 - If no path is available, c is blocked.
- III. $c(s, d)$ is in class C6:
 - Recall that two ordinary OXC nodes will not be clustered together if there is no attached MGOXC for them, even though they are neighbors.

Fig. 3. The GN -network produced from the NSF AS-HeteroWBS architecture, where the big gray circle is the G -node with MGOXC nodes, the small gray circle is the MGOXC node, and the small white circle is the OXC node.

- If s is the only node in the AS, adopt the k-shortest path algorithm and search for any available lightpath. If no path is available, c is blocked.
- If in node s 's AS, there is a set of MGOXCs $\{B_{i1}, \dots, B_{ij}\}$ and $j \neq 0$. Search for an active waveband-route from MGOXC node B_{ix} to d with an available wavelength λ such that λ is also available from s to B_{ix} , where $1 \leq x \leq j$.
- Otherwise, try to set up a new shortest waveband-path from B_{iy} to d with a free wavelength that is also available along the path from s to B_{iy} , where $1 \leq y \leq j$.
- Otherwise, adopt the k-shortest path algorithm and search for any available lightpath.
- If no path is available, c is blocked.

IV. $c(s, d)$ is in class C7 or C8:

- The same as for a call in class C6, except that d 's AS should be checked instead.

B. Autonomous Source-Limited Heterogeneous Waveband Switching (AS-S-WBS) Algorithm

The AS-S-WBS algorithm is only different from the AS-WBS algorithm in its routing. When a connection request of class C7 or C8 arrives, the source node delivers its connection request to the nearest attached MGOXC in the AS. After the MGOXC receives the connection request, it searches for the shortest path to the destination with a waveband-route along it. It also searches for a shortest-path from the source node to the MGOXC and combines the routes. For a connection request of class C1, C2, C5, or C6, the source node is the MGOXC. For a connection request of class C3 or C4, a shortest-path is assigned without any waveband-route.

C. Shortest-Path-Based Heterogeneous Waveband Switching (SH-WBS) Algorithm

We propose the SH-WBS algorithm based on the simplification of the AS-HeteroWBS architecture. As we mentioned an MGOXC should be connected with at least one other MGOXC to switch data in optical waveband signals and the MGOXCs comprise the BXC layer in the HeteroWBS network. Thus, we can construct a smaller *group-node network* (GN -network)

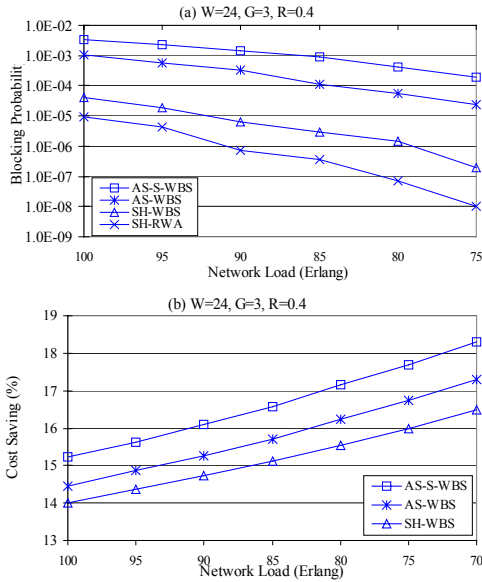

Fig. 4. Comparison of the algorithms under different network traffic loads (L), where W is 24, G is 3, and r is 0.4. (a) Comparison of the blocking probability. (b) Comparison of the cost saving ratio (%).

from the AS-HeteroWBS architecture by considering each AS as a single *group node* (*G-node*).

There are two types of *G-nodes* in the *GN-network*. One is with MGOXC nodes in its AS. The other is without any MGOXC node in its AS. The connectivity of a *G-node* in the *GN-network* is determined by the connections between the MGOXC nodes in the AS and the MGOXCs in other ASs. If the AS contains only one OXC node, the *G-node* connectivity is determined by the OXC node. The simplified *GN-network* for the NSF AS-HeteroWBS network is illustrated in Fig. 3, where the *G-nodes* with MGOXCs in their ASs are illustrated by big gray circles. After the *GN-network* is constructed, the nodes in the AS are connected to the *G-node*. As shown in Fig. 3, the MGOXC nodes are illustrated in small gray circles and the ordinary OXC nodes are illustrated in small white circles.

When a connection request of class C5, C6, C7, or C8 arrives, the SH-WBS algorithm searches for the shortest path between the two *G-nodes* in the *GN-network*. It then expands the real route in the original network by adopting the shortest-path algorithm. For the connection request of class C1, C2, C3, or C4, the SH-WBS algorithm searches for the shortest path in the original AS-HeteroWBS network. The wavelength assignment, waveband assignment, and the setting up of a new waveband-route are the same as the AS-WBS algorithm.

V. SIMULATION OF HETEROGENEOUS WBS NETWORKS

We employ the NSF HeteroWBS network with 6 MGOXC nodes and 8 OXC nodes shown in Fig. 2(a). The percentage of MGOXCs in the network is 43%. The AS-HeteroWBS network architecture is shown in Fig. 2(b). The *GN-network* is shown in Fig. 3. Poisson traffic is generated for the network with a rate λ . The traffic is uniformly distributed among the

Fig. 5. Comparison of the algorithms under different fiber capacities (W), where G is 4, L is 100 Erlang, and r is 0.4. (a) Comparison of the blocking probability. (b) Comparison of the cost saving ratio (%).

connection pairs. The call holding time is exponential with a mean time $\frac{1}{\mu}$. The network load in terms of Erlang is $L = \frac{\lambda}{\mu}$.

The following notations are used in this section. *AS_WBS*, *AS_S_WBS*, and *SH_WBS* represent the results obtained by adopting the AS-WBS algorithm described in Section IV-A, the AS-S-WBS algorithm described in Section IV-B, and the SH-WBS algorithm described in Section IV-C separately. *SH-RWA* illustrates the results obtained by the RWA algorithm adopting the shortest-path routing and the first-fit wavelength assignment without waveband switching.

We compare the three HeteroWBS algorithms and the RWA algorithm in terms of blocking probability and cost saving ratio. Simulations are conducted under different network loads in terms of Erlang: $L \in \{75, 80, 85, 90, 95, 100\}$, with different wavelength capacities per fiber link: $W \in \{16, 20, 24, 28, 32, 36, 40, 48, 56\}$, with different waveband granularities: $G \in \{2, 3, 4, 5, 6\}$, and with different ratios of wavelengths in wavebands: $r \in \{0.35, 0.4, 0.45, 0.55, 0.65\}$. Under each scenario and for each algorithm, we simulate 100,000,000 connection requests to obtain the results. The cost savings of a HeteroWBS algorithm are the savings of the utilized ports multiplied with the weighted cost associated with a port. There are two types of ports along a path. One is an OOO port with a weighted cost 0.2 along waveband-routes. The other is an OEO port with a weighted cost 1.0 along wavelength-routes. The cost saving ratio is obtained by dividing the cost saving due to WBS by the operational costs without WBS.

Fig. 4(a) compares the algorithms in terms of call blocking probability under different network traffic loads (L). As can be seen, the shortest-path-based HeteroWBS (SH-WBS)

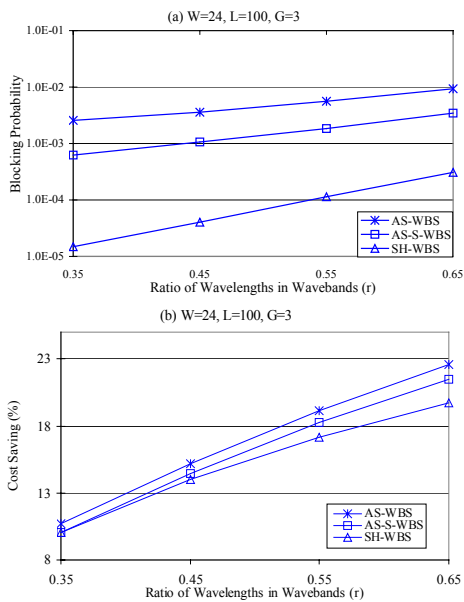

Fig. 6. Comparison of the algorithms under different ratios of wavelengths in wavebands (r), where W is 24, L is 100, and G is 3. (a) Comparison of the blocking probability. (b) Comparison of the cost saving ratio (%).

algorithm can achieve better performance than the other two HeteroWBS algorithms. Moreover, the results of the SH-WBS algorithm are very close to those of the RWA algorithm. By adopting the shortest-path routing only, the average path length for a connection is reduced compared with adopting the k-shortest path routing algorithm. Thus, the SH-WBS algorithm consumes fewer resources than the AS-S-WBS and the AS-WBS algorithms. In addition, all the results show that the blocking probability decreases as the network traffic load decreases. On the other hand, Fig. 4(b) illustrates that the AS-WBS algorithm and AS-S-WBS algorithm can achieve higher cost saving ratio than the SH-WBS algorithm. This is reasonable as the AS-S-WBS and the AS-WBS algorithms try to utilize WBS as often as possible for a connection. Moreover, the results show that the cost saving ratio increases as the traffic load decreases. The reason is that as the traffic load decreases, the ratio of successfully provisioned connections increases.

Fig. 5(a) compares the algorithms in terms of call blocking probability under different fiber capacities (W). Again, the SH-WBS algorithm performs better than the other two HeteroWBS algorithms and is close to the RWA algorithm. Moreover, the results illustrate that the blocking probability decreases as the fiber capacity increases. Meanwhile, Fig. 5(b) illustrates that the AS-WBS and the AS-S-WBS algorithms outperform the SH-WBS algorithm in cost savings. In addition, the results show that the cost saving ratio increases as the fiber capacity increases. This is because as the fiber capacity increases the number of wavebands along a fiber link increases given the fixed r and G . Moreover, the higher the fiber capacity is, the larger the performance gap becomes.

Fig. 6(a) compares the call blocking probability and Fig.

6(b) compares the cost saving ratio of the HeteroWBS algorithms when the ratio r changes. Again, the SH-WBS algorithm can achieve lower blocking probability and the AS-S-WBS and the AS-WBS algorithms can achieve higher cost savings. Moreover, the blocking probability slightly increases as the ratio r increases. Additionally, the higher the ratio r is, the higher the cost saving ratio that can be obtained. This is because as the ratio r increases the number of wavebands along a fiber link increases given the fixed W and G . Thus, the possibility of a call traversing a waveband-route increases.

VI. CONCLUSION

We investigated the waveband switching (WBS) problem under dynamic traffic requests in a heterogeneous waveband switching (HeteroWBS) network. In such a HeteroWBS network, some nodes are MGOXC with the WBS functionalities and some are ordinary OXC without the WBS functionalities. To screen the WBS information from the ordinary OXC nodes, an autonomous clustering-based heterogeneous waveband switching (AS-HeteroWBS) architecture was proposed, where a specific set of OXCs and MGOXCs is grouped into an autonomous system (AS). The MGOXC nodes in an AS are responsible for all the WBS functions in the AS. Three HeteroWBS algorithms were proposed based on the AS-HeteroWBS architecture. Substantial simulations showed that the HeteroWBS architecture is efficient to improve the WDM network performance.
