ABSTRACT

The impact of the leaf-chlorosis-eliciting Russian wheat aphid, Diuraphis noxia (Mordvilko), and the nonchlorosis-eliciting bird cherry-oat aphid, Rhopalosiphum padi (L.), feeding on D. noxia-susceptible and -resistant cereals was examined during the period (i.e., 3, 6, and 9 d after aphid infestation) that leaf chlorosis developed. After aphid number, leaf rolling and chlorosis ratings, and fresh leaf weight were recorded on each sampling date, total protein content, peroxidase, catalase, and polyphenol oxidase activities of each plant sample were determined spectrophotometrically. Although R. padi and D. noxia feeding caused significant increase of total protein content in comparison with the control cereal leaves, the difference in total protein content between R. padi and D. noxia-infested leaves was not significant. Although R. padi-feeding did not elicit any changes of peroxidase specific activity in any of the four cereals in comparison with the control leaves, D. noxia feeding elicited greater increases of peroxidase specific activity only on resistant ‘Halt’ wheat (Triticum aestivum L.) and susceptible ‘Morex’ barley (Hordeum vulgare L.), but not on susceptible ‘Arapahoe’ and resistant ‘Border’ oat (Avena sativa L.). D. noxia-feeding elicited a ninefold increase in peroxidase specific activity on Morex barley and a threefold on Halt wheat 9 d after the initial infestation in comparison with control leaves. Furthermore, D. noxia feeding did not elicit any differential changes of catalase and polyphenol oxidase activities in comparison with either R. padi feeding or control leaves. The findings suggest that D. noxia feeding probably results in oxidative stress in plants. Moderate increase of peroxidase activity (approximately threefold) in resistant Halt compared with susceptible Arapahoe wheat might have contributed to its resistance to D. noxia, whereas the ninefold peroxidase activity increase may have possibly contributed to barley’s susceptibility. Different enzymatic responses in wheat, barley, and oat to D. noxia and R. padi feeding indicate the cereals have different mechanisms of aphid resistance.

KEY WORDS

Diuraphis noxia, Rhopalosiphum padi, protein content, peroxidase, catalase, polyphenol oxidase

OXIDATIVE RESPONSES of plants to both abiotic (e.g., drought) and biotic (e.g., pathogens and herbivores) stresses have been reported on a number of crops. Drought stress increases peroxidase activities and malondialdehyde content (an indication of lipid peroxidation) in wheat plants (Zhang and Kirkham 1994). However, superoxide dismutase and catalase activities only increase at the early stage of drought conditions and then decrease under further drought conditions. The increase of peroxidase activities in rice, Oryza sativa L., wheat, Triticum aestivum L., barley, Hordeum vulgare L., cotton, Gossypium hirsutum L., and sugarcane, Saccharum spontaneum L., correlates with their resistance to pathogens (Chittoor et al. 1999). Pathogen-induced peroxidase activity is delayed or does not occur in the plants undergoing susceptible interactions. The activation of plant foliar oxidases by noctuid herbivore feeding reduces nutritive quality of foliage on both foliage and fruit of tomato plants, Lycopersicon esculentum Mill (Felton et al. 1989). Further experiments suggested that polyphenol oxidase, proteinase inhibitors, lipoygenase, and peroxidase decreased the nutritive value of tomato foliage to noctuid larvae (Duffy and Felton 1991, Duffy and Stout 1996). The incorporation of these enzymes into artificial diets reduces developmental performance of the noctuids. Insect feeding on soybean plants also elicited oxidative responses (Felton et al. 1994a, 1994b). Although a considerable amount of work has been reported on herbivores with chewing mouthparts, only a few studies have examined plant oxidative responses to sap-feeding insects. Feeding of twospotted spider mites, Tetramychus urticae Koch, on soybean, Glycine max (L.) Merr., elicits peroxidative responses in soybean leaves (Hildebrand et al. 1986), and resistance to T. urticae feeding and plant lipid peroxidation is strongly correlated in soybean genotypes. Both soybean resis-
tance and lipid peroxidation were also correlated to carotenoid and chlorophyll losses. The herbivory by the phloem-feeding, threecornered alfalfa hoppers, *Spissistilus festinus* (Say), causes increases in the activities of several oxidative enzymes including lipoxygenases, peroxidases, ascorbate oxidase, and polyphenol oxidase on soybean plants (Felton et al. 1994a, 1994b).

Although oxidative responses of plants to herbivore feeding have been examined in many plants, no comparable work has been reported for cereals. The current report is part of our ongoing research to understand the mechanism of leaf chlorosis development elicited by the Russian wheat aphid, *Diuraphis noxia* (Mordvilko), and the mechanisms of aphid resistance in cereal plants. The objective of the present investigation was to compare the oxidative responses of *D. noxia*-resistant and -susceptible cereals to the chlorosis-eliciting *D. noxia* and nonchlorosis-eliciting bird cherry-oat aphid, *Rhopalosiphum padi* (L.), feeding.

**Materials and Methods**

**Aphid Colony Maintenance.** ‘Stephens’ (*D. noxia* susceptible) wheat was used for aphid colony maintenance. Plants were grown in pots (10 cm diameter) in a mixture of Sunshine soil mix No. 1 (SunGro Horticulture, Bellevue, WA) and sand (6:1 ratio). The colony of chlorosis-eliciting *D. noxia* was established originally using *D. noxia* collected near Scottsbluff, NE, in 1994, and the nonchlorosis-eliciting *R. padi* colony was established using aphids collected near Lincoln, NE, in 1996. Plants and aphids were maintained in Plexiglas cages (30 by 15 by 15 cm) in Percival growth chambers (Percival Scientific, Boone, IA) at 21 ± 1°C, 40—50% RH, and a photoperiod of 16:8 (L:D) h.

**Growth of Cereal Plants.** The four cereals used in the experiment were *D. noxia*-susceptible ‘Arapahoe’ and -resistant ‘Halt’ wheat, *D. noxia*-susceptible ‘Morex’ barley, and *D. noxia*-resistant ‘Border’ oat, *Avena sativa* L. There were no previous reports on either resistance or susceptibility of *R. padi* to the four cereals used in this study. The impact of aphid feeding on cereal leaf total protein content, peroxidase, polyphenol oxidase, and catalase activities were examined spectrophotometrically. Changes in enzyme activities were monitored 3, 6, and 9 d after the initial aphid infestation, which accompanied the development of *D. noxia*-elicited leaf rolling and chlorosis on the susceptible cereals.

Seeds of Arapahoe and Halt wheat, Morex barley, and Border oat were thinned at the rate of three plants per Conetainer (SC-10 Super Cell Single Cell, 3.81 cm diameter by 21 cm deep, Stuewe & Sons, Corvallis, OR) in the Plant Growth Center, Montana State University, Bozeman, MT. The Conetainers were filled with the previously described soil mixture and placed in Conetainer racks, leaving one space between two Conetainers to provide adequate light. Plants were watered uniformly from the bottom by placing a rack over a plastic tray (54 by 28 by 6 cm) filled with water.

Before the initiation of aphid infestation, plants were thinned to one plant per Conetainer. Plants used in the experiment were grown under the conditions described above.

**Infestation of Cereal Plants.** At growth stage 12 (or two-leaf stage) (Zadoks et al. 1974), the second leaf of the cereal plants was infested with 0, 20 apterous adult *R. padi*, or 20 apterous adult *D. noxia*. Aphid-infested plants were sampled on 3, 6, and 9 d after the initial infestation. All control and aphid-infested cereal plants were caged individually using polyethylene tube-cages (30 cm long by 4 cm diameter) and maintained in a Percival growth chamber under the conditions described above. On each sampling date, three plants (considered replications) were randomly selected for each of the 12 treatments (four cereals by three infestation levels). The number of aphids on the young leaf blade used for the enzyme assays (per leaf) and on the whole seedling (per plant) was recorded before removal. Aphid damage symptoms (leaf rolling and chlorosis) were then rated according to Webster et al. (1991) and Burd et al. (1993). The same-age young leaf blades were excised and weighed for the following protein and enzyme assays, because the young leaves had shown the most *D. noxia* damage.

**Preparation of Leaf Tissue for the Assays.** Excised leaf tissue was processed following the protocol described by Hildebrand et al. (1986). Cold potassium phosphate buffer (0.1 M, pH 7.0) containing 1% (wt:vol) polyvinylpyrrolidone and 1% (vol:vol) Triton X-100 was added to a chilled (4°C) mortar and pestle containing the excised leaf sample. The leaflets were macerated with 1 ml of the extracting buffer. Samples were further ground with another 1 ml of the extracting buffer. In total, 2 ml of the extracting buffer was used for each sample. An aliquot (1.5 ml) of the extract was centrifuged at 10,000 × g for 10 min at 4°C. The supernatant was frozen immediately for future total protein content and enzyme activity assays.

**Protein and Enzyme Assays.** The assays for total protein content and three oxidative enzymes (i.e., peroxidase, catalase, and polyphenol oxidase) were performed using a Genesys 5 spectrophotometer (Spectronic Instruments, Rochester, NY). All chemicals used in these assays were purchased from either Sigma Chemicals (St. Louis, MO) or Fisher (Houston, TX).

Total protein content was determined in duplicate using the Bradford assay described by Bollag and Edelstein (1991). Briefly, the assay mixture was made of 295 μl of potassium phosphate buffer (0.1 M, pH 7.0), 500 μl distilled water, 200 μl Bradford reagent, and 5 μl of the plant extract. The absorbance of the assay mixture was recorded at 595 nm. Total protein content was calculated using a standard curve generated from a series of bovine serum albumin concentrations (i.e., 0, 2.5, 5.0, 7.5, 10, and 12.5 μg/ml).

Peroxidase activity was determined by monitoring the increase in absorbance at 470 nm for 2 min at room temperature using a modified protocol described by Hildebrand et al. (1986) and Hori et al. (1997). The reaction was initiated by adding 200 μl of 0.3% hy-

Means without standard error of mean ± SEM denoted SEM = 0. The means listed in the table were calculated from three samples (n = 3). The means with different letters (a-c) within a column under each category were significantly different, whereas R. padi and D. noxia means with different letters (X-Y) within the same sampling date were not significantly different (LSD, α = 0.05).

Results

Aphid Population Development. Because cereal- by-infestation-by-sampling date interaction did not significantly (F = 0.62; df = 6, 32; P = 0.7109) affect the number of aphids per leaf, main effect of each experiment factor was analyzed. Although the sampling date (or infestation duration) (F = 10.22; df = 2, 32; P = 0.0004) showed a significant effect on aphid number per leaf, cereal type did not affect aphid population growth (F = 0.35; df = 3, 6; P = 0.7929). The total number of aphids per plant was similar to the number of aphids per leaf. The cereal-by-infestation-by-sampling date interaction was not significant (F = 1.74; df = 6, 32; P = 0.1434), while the sampling date showed a significant effect on aphid numbers per plant (F = 10.22; df = 2, 32; P = 0.0004). But, neither aphid species (F = 1.86; df = 1, 6; P = 0.2102) nor did cereal type (F = 1.96; df = 3, 6; P = 0.2219) affect the total number of aphids per plant.

The increase of aphid numbers occurred through the three sampling dates was likely the result of natural aphid population development that differed in the two species. Greater variation in the number of aphids per plant in both species was observed on the 9-d sampling

Fresh leaf weight, g

Table 2. Leaf rolling and chlorosis ratings and fresh weight (±SEM) of the leaf blades used in enzyme assays

Means without standard error of mean ± SEM denoted SEM = 0. The means listed in the table were calculated from three samples (n = 3). The means with different letters (a-c) within a column under each category were significantly different, whereas the means with different letters (X-Y) within the same sampling date were not significantly different (LSD, α = 0.05).
a significant increase of total protein content in comparison with the control, there was no significant difference in protein content between R. padi- and D. noxia-infested leaves ($F = 3.51; \text{df} = 1, 16; P = 0.0981$) (Fig. 1). Cereal type also influenced leaf protein content significantly ($F = 11.67; \text{df} = 3, 6; P = 0.0065$). The wheat leaves (Fig. 1 A and B) had higher protein content than the barley (Fig. 1C) and oat leaves (Fig. 1D).

Peroxidase Activity. Although the cereal-by-infestation-by-sampling date interaction ($F = 1.56; \text{df} = 12, 48; P = 0.1345$) and the sampling date ($F = 0.003; \text{df} = 2, 48; P = 0.9974$) did not significantly affect peroxidase specific activity, the infestation type ($F = 46.40; \text{df} = 3, 6; P < 0.0001$) and cereal type ($F = 13.40; \text{df} = 3, 6; P < 0.0045$) had significantly affected the peroxidase activity. D. noxia infestation caused greater increase of peroxidase activities on Halt wheat and Morex barley than on Arapahoe wheat and Border oat in comparison with the control and R. padi-infested leaves (Fig. 2). Of the four cereals tested, susceptible Arapahoe wheat showed less D. noxia-elicited increase (Fig. 2A) than resistant Halt wheat (Fig. 2B). The peroxidase activity increased as D. noxia infestation continued on Halt wheat (Fig. 2B) and Morex barley (Fig. 2C). D. noxia-infested Morex barley leaves showed the greatest increase of peroxidase activities, as high as ninefold, when compared with the control on day 9 (Fig. 2C). D. noxia-infested Halt wheat showed approximately threefold increase in peroxidase activity on day 9. In contrast, Border oat showed no significant increase of peroxidase activity on any sampling dates (Fig. 2D). The increase of peroxidase activity in D. noxia-infested wheat and barley accompanied the damage symptom development (Fig. 2 B and C) on 6- and 9-d sampling dates, but not in Arapahoe wheat and Border oat (Fig. 2 A and D).

Catalase Activity. In addition, the cereal-by-infestation-by-sampling date interaction showed no effect on catalase activity ($F = 0.44; \text{df} = 12, 48; P = 0.9377$), neither infestation type ($F = 1.38; \text{df} = 2, 16; P = 0.2798$) nor cereal type ($F = 1.80; \text{df} = 3, 6; P = 0.2475$) have any effect on catalase activity. However, catalase activity decreased significantly among the three sampling dates ($F = 31.44; \text{df} = 2, 48; P < 0.0001$) on all four cereals and all three infestations (Fig. 3). The results indicate that neither R. padi nor D. noxia feeding affected catalase activity in cereal leaves.

Polyphenol Oxidase Activity. As with catalase activity, polyphenol oxidase activity was not significantly affected by either three-way (i.e., cereal-by-infesta-
tion-by-sampling date) interaction ($F = 0.61; df = 12, 48; P = 0.8220$), or infestation type ($F = 2.85; df = 2, 16; P = 0.0876$), or cereal type ($F = 4.04; df = 3, 6; P = 0.0687$) (Fig. 4). Polyphenol oxidase activity also varied significantly among the sampling dates ($F = 32.47; df = 2, 48; P < 0.0001$). The leaves from the first sampling date (3 d) showed the highest polyphenol oxidase activity, whereas the leaves from the last sampling date (9 d) showed the least polyphenol oxidase activity. The results indicate that the types of infestations did not have any significant impact on polyphenol oxidase activity. The decrease in both catalase and polyphenol oxidase activities among the sampling dates might be the result of normal cereal leaf growth.

Discussion

*Diuraphis noxia* caused more damage than *R. padi* on Arapahoe wheat and Morex barley measured by leaf rolling and chlorosis ratings and fresh leaf weight in comparison with Halt wheat and Border oat. This supports our previous finding that *D. noxia* prefers to feed and reproduce more nymphs on the susceptible Arapahoe wheat and Morex barley than on the resistant Halt wheat and Border oat (Ni et al. 1998). Furthermore, aphid population data showed that *D. noxia*-resistant Halt wheat might not necessarily be *R. padi*-resistant. This observation needs to be further examined.

Although *D. noxia* is a chlorosis-eliciting species and *R. padi* is a nonchlorosis-eliciting species, their feeding caused similar increases in total leaf protein content on all cereals regardless of their degree of resistance to *D. noxia*. This finding indicates that both symptomatic and asymptomatic aphid feeding induces protein biosynthesis in cereals, and is in concurrence with previous reports on plant defensive responses to pathogens and other herbivores. The induction of proteins in plant tissues by infestations of herbivores or infections of pathogens has been demonstrated by numerous studies, and this special type of the protein has been termed “pathogenesis-related” (or PR) protein (Hildebrand et al. 1989, Hammerschmidt and Nicholson 1999). The increase in total protein content of aphid-infested cereals compared with the control cereals suggests that aphid feeding induced local accumulation of proteins on aphid-infested cereal leaves.
The induction of protein content in aphid-infested leaves indicates that plants are likely to show enzymatic responses to aphid feeding. However, our findings disagree with the report by Van der Westhuizen and Pretorius (1995) who demonstrated that *D. noxia* feeding elicited more than a twofold water soluble protein content reduction as early as 2-d infestation when it was compared with the control leaves. The difference between our report and that of Van der Westhuizen and Pretorius (1995) could be the result of different initial aphid infestation levels. We used 20 apterous *D. noxia* for the current study, however, the level of the initial aphid infestation was not described by Van der Westhuizen and Pretorius (1995).

The increase in peroxidase activity occurred before leaf chlorosis development on *D. noxia*-infested Halt wheat and Morex barley leaves. This finding indicates that damage symptom development on these two cereals may be related to *D. noxia*-elicited plant oxidative responses, because the nonsymptomatic *R. padi* did not elicit any significant increases of oxidative enzyme activities. The findings from the current study support a number of previous reports that have demonstrated that oxidative enzymes (e.g., peroxidase, catalase, and polyphenol oxidase) in plants play an important role in responding to biotic and abiotic stresses (Hildebrand et al. 1986; Zhang and Kirkham 1994; Felton et al. 1994a, 1994b). In addition, Duffey and Felton (1991) have demonstrated in vitro that the peroxidase activity is dependent on a supply of hydrogen peroxide. The production of radical or reduced intermediates (e.g., hydrogen peroxide, superoxide, and the hydroxyl radicals) in plants is the result of metabolic reactions involving oxygen (Daub et al. 1998). To understand hydrogen peroxide production in plants, further examination of superoxide dismutase and other related enzyme activities will be necessary because superoxide dismutase is responsible for scavenging reactive oxygen intermediates in plants to form hydrogen peroxide.

A number of reports have suggested that peroxidases play an important role in both herbivore and pathogen resistance in crop plants (Dowd and Lagrimini 1997, Chittoor et al. 1999, Constabel 1999). Peroxidases are the key enzymes in plant cell wall-building processes, such as peroxidase-mediated oxidation of hydroxycinnamyl alcohols into free radical intermediates, phenol oxidation, polysaccharide cross-linking, cross-linking of extensin monomers, lignification, and suberization (Chittoor et al. 1999). The final products of such enzymatic activities would be considered anti-nutritive (or anutritive) because they cannot be

---

**Fig. 3.** Catalase specific activity (pmol min$^{-1}$ 6 mg protein$^{-1}$) from aphid-infested (i.e., 0, 20 *R. padi*, or 20 *D. noxia*) cereal leaves on 3, 6, and 9 d after the initial infestation. Error bars represent standard error of the mean (SEM) for a data point ($n = 3$). (A) Arapahoe wheat (*D. noxia* susceptible). (B) Halt wheat (*D. noxia* resistant). (C) Morex barley (*D. noxia* susceptible). (D) Border oat (*D. noxia* resistant). *R. padi* denotes the bird cherry-oat aphid, *Rhopalosiphum padi* L., and *D. noxia* denotes the Russian wheat aphid, *Diuraphis noxia* (Mordvilko).
efficiently digested and assimilated by insects (Duffey and Stout 1996, Constabel 1999). Enhancement of peroxidase isozyme activity in maize (Zea mays L.) increases resistance to herbivores and pathogens (Dowd and Lagrimini 1997). However, Dowd and Lagrimini (1997) state that peroxidase functions in plants are complicated and the role of peroxidase in plant resistance to its pests is sometimes controversial because variations have been observed among different plant–insect systems, as well as laboratory studies may not reflect field conditions. Our data reflect these contrasting paradigms; for instance, D. noxia-infested Border oat plants showed the least changes of peroxidase, catalase, and polyphenol oxidase activities when compared with wheat and barley. Thus, D. noxia-resistant mechanism in Border oat is not necessarily related to oxidative enzymes. Wheat resistance to D. noxia is likely to be positively correlated to peroxidase activity because D. noxia-infested resistant Halt showed a greater peroxidase activity than susceptible Arapahoe. Conversely, Morex barley susceptibility is likely to be positively related to the increase of peroxidase activities. Such contrasting differences between D. noxia-resistant Halt wheat and D. noxia-susceptible Morex barley may be the result of genetic differences in their metabolic pathways to scavenge oxidative radicals. The interruption of the balance of reduction and oxidation functions (i.e., redox system) in plants against sap-feeding insects has been designated as “the redox hypothesis” in aphid–plant interactions (Miles and Oertli 1993). Although Miles and Oertli (1993) suggest that the change of oxidative activities is a natural part of plant defense against insect herbivory, the findings of our current study using the chlorosis-eliciting D. noxia and the nonchlorosis-eliciting R. padi indicate that cereal plant resistance against the aphid feeding might be complicated biochemical processes that need to be further examined. The results from this experiment will serve as the baseline information for us to understand the proteins involved in the defensive responses of plants to sap-feeding herbivores, and to ultimately identify enzymatic marker(s) for the screening of plant germplasms for herbivore resistance.
