Growth Analysis Based on Degree Days

M. P. Russelle, W. W. Wilhelm, R. A. Olson, and J. F. Power

ABSTRACT

Comparisons of growth analysis functions within and among experiments are often confounded by sources of variation other than those imposed by treatment. We suggest use of a temperature index, such as modified growing degree days, as the divisor in growth functions to facilitate treatment comparisons within certain experiments and to reduce the effects of differing temperature regimes among experiments on these comparisons. Three experiments were identified to provide data to analyze this new approach. Mean absolute growth rate (GR) and mean relative growth rate (RGR) were compared in two experiments with maize (Zea mays L.) conducted in eastern Nebraska. Previously published values of RGR and mean net assimilation rate (NAR) of barley (Hordeum vulgare L.) grown under controlled environments in a soil temperature and P fertility study were also evaluated. Use of modified growing degree days, rather than days, as the divisor in these growth functions led to the recognition of physiological differences due to or associated with treatment, which were previously masked by normal crop response to temperature, and clarified other treatment differences by reducing the effect of temperature.

Additional index words: Barley, Growth functions, Growth rate, Heat units, Hordeum vulgare L., Maize, Net assimilation rate, Relative growth rate, Zea mays L.

Rates of most biological processes are affected markedly by temperature. Growth and development of whole organisms show a temperature response which results from the integrated effect of temperature on the many individual physiological processes involved.

Neild and Seeley (22) quoted the report by Reamur in 1735 that plant development was not as closely related to time as to accumulated temperature. Numerous studies have demonstrated the usefulness of temperature indices, like growing degree days or heat units, for predicting crop growth and development, classifying crop species, hybrids and varieties, or evaluating climates for specific crop-management combinations (2, 7, 9, 11, 22, 25, 28). Most proposed temperature indices show significantly greater correlation with plant growth and development than does accumulated time, although differences in the relationship among temperature indices are slight (6, 7, 9, 12, 20, 27).

Plant growth and development are certainly affected by factors other than temperature, such as flux and duration of photosynthetically active radiation, availability of nutrients and water, and loss of photosynthetic tissue. Day length plays a well-known, integral part in induction and initiation of flowering in many species (4). However, even with maize (Zea mays L.) grown under field conditions, for example, temperature indices alone can often explain over 95% of the variability in development (20, 22).

Despite general acceptance of this close relationship, the use of temperature indices has not been generally extended to growth analysis. Growth analysis has been a valuable tool in the quantitative analysis of plant and crop growth since the suggestion by Blackman in 1919 (5) that growth generally follows the compound interest law. He used absolute growth rate (GR), relative growth rate (RGR), leaf area ratio (LAR), net assimilation rate (NAR), and other similar functions to describe plant growth. Growth analysis can be approached on an individual plant or areal basis.

The growth functions, GR, RGR, and NAR, increase with temperature and light flux within a range specific for a given crop (29, 30, 31). Growth functions calculated in the traditional manner will necessarily include the effect of controlled and uncontrolled environmental variables.

The purpose of calculating growth functions is generally to describe or explain how one or more plant species respond to a given environmental situation. In many experiments, environmental conditions will vary considerably among years and will vary within any one year for different treatments, such as planting date or location. These environmental variables confound comparisons of growth functions for crops having the same treatment regime over two or more years or for crops having different treatments in the same season. Calculations based on time may be appropriate for an experimental as long as it is recognized that environmental conditions are confounded with species and treatment. However, in experiments designed to make comparisons of physiological response, growth functions ideally should be independent of environmental variables. Comparisons of growth functions within and among different experiments would be less ambiguous if sources of variation other than imposed treatments could be eliminated.

We suggest that growth analysis functions be calculated using a temperature index as the divisor, rather than using time. In a survey of growth analysis literature (1, 8, 10, 13, 15, 18, 24, 26, 32, 33), we found only three references in which a temperature index was used to calculate growth rate. Hawkins and Cooper (15) calculated GR as g plant⁻¹ Cd⁻¹, where Cd was the product of days and average daily air temperature above a base of 9°C. Grain GR was based on a temperature index in two articles (1, 8). Our suggested approach is to define

\[ GR_M = \frac{(W_2 - W_1)}{(M_2 - M_1)} \]

and

\[ RGR_M = \frac{(\log_e W_2 - \log_e W_1)}{(M_2 - M_1)} \],

where \( W_1 \) and \( W_2 \) are dry weights of plant samples at two successive sampling times, and \( M_1 \) and \( M_2 \) are...
a temperature index, such as modified growing degree days, from some common date such as planting or emergence to the respective dates of sampling. Growth analysis formulae calculated in this manner should be designated by the subscript "M" for modified growing degree days to differentiate them from time-based formulae. The \( \text{NAR}_M \) should be calculated only after establishing the relationships between leaf area (A) and dry weight (W), since the appropriate form of the equation depends upon this relationship (24). However, the chosen temperature index would be used as the divisor. The objective of this paper is to demonstrate the use of temperature index as opposed to time as the divisor in growth analysis functions, using data from three previously completed experiments.

**MATERIALS AND METHODS**

To show the effect of using a temperature index rather than time in the calculation of growth functions, we applied standard analyses of variance to data from two field experiments conducted in eastern Nebraska by the authors, both involving maize. Experiment I was conducted near Lincoln, Nebr., on a Butler silty clay loam (fine, montmorillonitic, mesic Acrudult Argiaqualfs) on rain-fed maize (cv. Neb 620) planted in each of 2 years on plots subjected to tillage treatments. All plots received a uniform application of 70 kg N ha\(^{-1}\) as \( \text{NH}_4\text{NO}_3 \) and were replicated four times. Plant samples (four from each replication) were procured from each treatment for dry matter determination at 5-leaf, 11- to 12-leaf, blister, hard-dough, and physiological maturity stages in 1977, and 4-leaf, 12- to 15-leaf, blister, hard-dough, and physiological maturity stages in 1979. Experiment II was conducted near Mead, Nebr., on a Sharpsburg silty clay loam (fine, montmorillonitic, mesic Typic Argiudolls) and included early and late planting (late April and late May 1980, respectively) of irrigated maize (cv. Neb 714) with a factorial combination of two N rates at four application times. Three plants from each of four replications were sampled at 8-leaf, 12-leaf, silking, soft-dough, and physiological maturity [stages 2, 3, 5, 7, and 10, respectively (14)]

Aboveground dry weights were determined for individual plants after drying at 70°C, and calculations of GR, \( \text{RGR}_M \), and \( \text{RGR}_M \) were made for both experiments. Standard analyses of variance were computed for all functions. In Exp. I, treatments were sampled on the same date, so only the comparisons of growth functions between years are discussed here. In Exp. II, all N treatments within a planting date were sampled at the same time, so conversion of GR and \( \text{RGR}_M \) to \( \text{GRM}_M \) and \( \text{RGRM}_M \), respectively, did not change these comparisons. Because differences between the analyses were statistically significant only between planting dates, only these means are examined here.

Also evaluated were data published by Power et al. (23) on barley (Hordeum vulgare L.) grown in controlled environmental chambers on Parshall fine sandy loam (coarse-loamy, mixed Pachic Haploborolls) topsoil at two P fertilization rates (6.8 and 44.0 mg P kg\(^{-1}\)), constant air temperature (29°C), and constant soil temperatures of 9.0, 15.5, or 22.0°C (Exp. III). Dry-matter and leaf-area determinations were made at the 3-leaf, 4-leaf, tillered, headed, soft-dough, and maturity stages [corresponding to stages 1 to 6, respectively (23)]. The \( \text{NAR} \) and \( \text{RGR} \), calculated by

the original authors on a time basis, were compared with \( \text{NAR}_M \) and \( \text{RGR}_M \).

The temperature index chosen was modified growing degree days (12), which was calculated from date of planting or emergence to the date of sampling by summing the following value for each day

\[
M = [(T_{\text{max}} + T_{\text{min}})/2] - T_b,
\]

where M was the degree days for a given day, \( T_{\text{max}} \) was the maximum daily air temperature with an upper limit of 30°C, \( T_{\text{min}} \) was the minimum daily air temperature with a lower limit of 10°C, and \( T_b \) was equal to 10°C for Exp. I and II. Air temperatures were recorded for nearby U.S. Weather Bureau stations at the Lincoln Municipal Airport and the Mead Agronomy Laboratory for Exp. I and II, respectively.

This index was very closely related to maize development until silking (\( r^2 = 0.98, P < 0.01 \)). In Exp. III, soil temperature was used instead of air temperature. Because air temperature was constant throughout the experiment, daily

\[
M = T_b - T_s,
\]

where \( T_s \) was the soil temperature (9.0, 15.5, or 22.0°C), and \( T_b \) was 5°C (21). Inspection of the resulting values made it clear that a maximum limit to the average \( T_s \) was required. This limit was set at 10°C for reasons given in the next section.

**RESULTS AND DISCUSSION**

In Exp. I, yearly differences between \( \text{GR} \) and \( \text{GR}_M \) were similar (Table 1). The significantly lower growth rates during 1977 compared to 1979 resulted from extreme drought during the 1976 growing season (May to September precipitation 45% below normal), little precipitation during the 1976 to 1977 winter (October to April, 29% below normal), and only one rainfall event greater than 25 mm in the 40 days prior to tasseling in 1977. Although water stress limited \( \text{GR} \) and \( \text{GR}_M \) during 1977, the comparison of \( \text{RGR} \)

‡ Divisors used to calculate functions for each interval.

Fig. 1. Meteorological data and growth stage observations from 9 June to 6 July 1980 for Exp. II. The symbols, E2, L2, E3, and L3, indicate the dates when early- and late-planted maize reached growth stages 2 and 3 (8- and 12-leaf, respectively).
and $RGR_M$ indicated the use of M as the divisor accounted for differences in growth between the 2 years during some of the growth stage intervals (1 to 3 and 6 to 8). This suggested that variation in environmental factors other than temperature limited during growth stage interval 3 to 6.

Very large differences in total M between similar stage at different temperature treatments were obtained when $T_S$ was not limited. Barley grown at 9.0°C required 368 M to reach maturity after transplanting [i.e., with $T_B = 5°C$, 92 days $\times 4°C$ (23)]. Barley required only 78 days to mature at both higher temperatures. The disparity in total M among temperatures can be alleviated by setting the upper limit of $T_S$ at 10°C [i.e., (368 M/78 days) + $T_B$, rounded to 10°C for calculations]. Need for a correction for excessive soil temperature appeared to be justified by the final dry-matter production, which was 17.2, 18.3, and 15.4 g pot$^{-1}$ for 9.0, 15.5, and 22.0°C, respectively. This trend would also suggest a limit for $T_S$ between 9.0 and 15.5°C. In contrast, maize dry matter accumulation tended to decrease at soil temperatures greater than 15.0°C (3).

Statistical evaluation of the RGR and $RGR_M$ values was not possible because only treatment means were reported by the authors (23). Temperature did not affect NAR, but use of NAR$M$ decreased the ratio of high to low values across temperature treatment and maintained the ratio across P treatments (Table 4). These results clearly indicate the value of our approach.

For simplicity, only temperature was included in our calculations. Measurements of light flux and duration, though easy to make with modern instru-

4 $M = T_S - T_B, T_B = 5°C, T_S \leq 10°C$. 

---

The comparison of days and M as divisors in growth function calculations in Exp. III was dramatic when no upper limit was set for soil temperature, and resulted in a complete reversal in pattern of $RGR_M$ (Table 3). According to the general concept of growing degree days, total M between specific stages of development should not vary significantly with temperature. Very large differences in total M between similar stage at different temperature treatments were obtained when $T_S$ was not limited. Barley grown at 9.0°C required 368 M to reach maturity after transplanting [i.e., with $T_B = 5°C$, 92 days $\times 4°C$ (23)]. Barley required only 78 days to mature at both higher temperatures. The disparity in total M among temperatures can be alleviated by setting the upper limit of $T_S$ at 10°C [i.e., (368 M/78 days) + $T_B$, rounded to 10°C for calculations]. Need for a correction for excessive soil temperature appeared to be justified by the final dry-matter production, which was 17.2, 18.3, and 15.4 g pot$^{-1}$ for 9.0, 15.5, and 22.0°C, respectively. This trend would also suggest a limit for $T_S$ between 9.0 and 15.5°C. In contrast, maize dry matter accumulation tended to decrease at soil temperatures greater than 15.0°C (3).
The choice of a particular temperature index as the divisor in growth functions will depend on the availability and type of temperature data and on the cardinal temperatures for the crop in question. It is important to use an index which is defined for the reader, is more closely related than time to observed plant growth, and includes well estimated cardinal temperatures. Use of M as the divisor in growth functions should not increase experimental error, if this procedure is followed. The coefficients of variation of calculation were within 2 percentage points of each other in Exp. I and II (data not shown). It is preferable to use canopy temperatures to air temperatures, when the former are available.

Use of a temperature index as the divisor in growth analysis formulae is not limited to sampling at predetermined growth stages or to comparisons of mean growth functions within an experiment. Continuous functions could be calculated with a temperature index using regression analysis (17, 19). Because of the close relationship between temperature and crop development, the use of a temperature index in these formulae should make comparisons among and within experiments more meaningful. We anticipate that use of this method may lead to the recognition of physiological responses to treatment previously masked by normal (and expected) crop response to changing temperature.
