Cardiovascular Fitness Moderates the Relations Between Estimates of Obesity and Physical Self-Perceptions in Rural Elementary School Students

Nathanael G. Mitchell, Justin B. Moore, Wendy S. Bibeau, and Kathleen M. Rudasill

Background: Levels of physical activity decline throughout childhood. Children's physical self-perceptions have been found to relate to their physical activity. Understanding the relationships among physical self-perceptions, obesity, and physical activity could have important implications for interventions in children.

Methods: The current study investigated the moderating effect of cardiovascular fitness (CVF, heart rate recovery from a 3-minute step test) on the relationship between obesity (BMI, waist circumference) and physical self-perceptions (athletic competence, physical appearance) in 104 fourth- and fifth-grade children from a small rural community. **Results:** Hierarchical regression analyses indicated that CVF moderated the relations between BMI and waist circumference on athletic competence. For children with lower fitness, higher waist circumference was associated with lower athletic competence, while for children with higher fitness levels, higher BMI was associated with higher athletic competence. Results also indicated that both BMI and waist circumference were negatively related to physical appearance. CVF moderated these relations such that only children with lower fitness, greater BMI and waist circumference was associated with poorer physical appearance scores. **Conclusions:** Implications include the need for support of fitness programs to promote psychological well-being and to investigate the relationship between obesity and physical self-perceptions within the context of fitness.

Keywords: body composition, exercise psychology, pediatrics, physical fitness

Children's physical activity levels have declined steadily over the last several decades.¹ Physical activity declines dramatically during late childhood and pre-adolescence, with the declines especially pronounced in females.²⁻⁴ Researchers have posited that to develop effective physical activity interventions for children, an understanding of psychological and cognitive variables related to physical activity must be investigated.^{5,6} Further, the social cognitive theory (SCT)⁷ is an oft cited theory when addressing physical activity and health behaviors in children. A core element of SCT is *reciprocal determinism*, which states that there are constant, dynamic, causal interactions between a child's environmental, behavioral, and personal factors. Children's

self-perceptions (eg, self-efficacy, outcome expectations) are integral in influencing their choice to initiate and maintain physical activity. Indeed, previous research has found a link between children's physical self-perceptions and their physical activity, such that more positive physical self-perceptions are related to higher levels of physical activity. In addition, Dishman and colleagues⁸ found a direct causal link between social-cognitive variables and an increase in physical activity in adolescent girls. Further research is needed to understand the relations between children's self-perceptions, physical activity, and body size.

The increasing prevalence of obesity in children in the U.S. has become a major public health concern, as prevalence rates across all age groups continue to increase. The percentage of overweight children age 6 to 11 years rose from 28.2% in 1999 to 33.6% by 2004.⁹ Research suggests that rural children may be at particular risk for obesity.¹⁰⁻¹² According to the "F as in Fat" Report, Kentucky ranks fourth in the United States for prevalence of overweight and obese youth age 10 to 17 years, impacting nearly 37.1% of the population of children in this age range. It is important to study the physical and psychological variables that may assist in developing programs to decrease obesity in such high-risk populations.

Research indicates children's obesity is related to how they feel about themselves physically,^{13,14} with heavier children reporting poorer perceptions of their athletic abilities and physical appearance.¹³⁻²⁰ Despite the prevalence and increased risk of obesity in rural communities, few studies have been conducted to investigate the relationship between estimates of obesity and self-perceptions among rural children. Related to self-perceptions of physical appearance, Packard and Krogstrand²¹ investigated the weight concerns of girls age 8 to 17 from rural communities in the Midwest. Their results indicated that more than 60% of girls age 8 to 10 expressed weight concerns, specifically the desire to be thinner. Welch and coworkers²² examined the relation between body image perceptions and obesity, as measured by BMI, in a sample of fourth graders in Maryland. The schoolchildren were sampled from urban, suburban, and rural locations. When comparing those who were categorized as overweight with their healthy weight peers, rural students expressed more body dissatisfaction than urban students. These few studies represent the beginnings of a necessary line of research investigating the relationship between estimates of obesity and the physical self-perceptions of children at greater risk of obesity due to their particular geographic location.

In addition, in a recent literature review of the psychological impact of obesity in children, Wardle and Cook²³ questioned the lack of consistency and small effect sizes in previous research investigating the link between children's obesity and self-perceptions. One possible explanation for inconsistent findings linking these constructs may be the use of BMI as the primary estimate of obesity. BMI may not reflect a child's true physical condition because BMI does not accurately distinguish between lean muscle mass and fat mass, nor does it reveal distribution of obesity. In an effort to better assess fat distribution and its potential health effects, medical and physiological researchers often use other indicators of obesity such as waist circumference when examining associations between obesity and disease risk factors.²⁴⁻²⁶ Furthermore, the measurement error associated with BMI may not allow researchers to fully understand the relationship between the physical condition of a child and his or her physical self-perceptions. For example, the impact of obesity on self-perceptions for a child with a large belly that is disproportionate to the rest of his or her body may be different from a child who is large but proportioned more evenly and comparably to his or her peers. Therefore, the current study employs 2 measures of obesity: BMI and waist circumference. Wardle and Cook²³ urged researchers to examine possible moderators of the relation between children's obesity and psychological functioning, including self-perceptions. One such potential moderator may be children's cardiovascular fitness (CVF). Children's CVF has been shown to contribute to children's physical self-perceptions. Husenblaus and colleagues²⁷ found a significant relationship between cardiovascular fitness

and evaluations of the physical self; specifically, children with lower CVF levels reported lower satisfaction with themselves physically. Similarly, a study revealed that a physical fitness intervention with fourth-grade Hispanic children increased children's fitness and improved physical self-perceptions.²⁸ These studies represent the small body of literature linking CVF to children's physical self-perceptions. However, there is a dearth of literature considering the cardiovascular fitness of children as a potential moderator of the relationship between estimates of obesity and children's physical self-perceptions.

The link between estimates of obesity and children's physical perceptions may contrast greatly depending on children's cardiovascular fitness. The physical self-perceptions of a child who is both fit and has higher estimates of obesity (eg, a football player on the offensive line) may contrast greatly with the physical self-perceptions of a child who is less fit and also has high estimates of obesity. Having higher estimates of obesity may have a more negative impact on physical self-perceptions for a child who becomes out of breath after climbing a flight of stairs compared with a child who is able to play sports or join his or her friends in physically challenging activities. It is also particularly important to understand this relationship for children who, for various reasons, are at higher risk for obesity. Children in rural areas of Kentucky comprise such an at-risk sample.

Therefore, the current study seeks to understand the relationships between various estimates of obesity, children's physical self-perceptions, and the moderating effect of cardiovascular fitness on these relationships in rural elementary school children. The current study was designed to test examine the following research questions and test the following hypotheses: First, are BMI and, waist circumference associated with rural children's physical self-perceptions (ie, athletic competence, physical appearance)? It was hypothesized that both estimates of obesity (ie, BMI, waist circumference) would have significant, negative relationships with physical self-perceptions. Second, does cardiovascular fitness moderate relations between the 2 estimates of obesity and children's physical self-perceptions? It was hypothesized that CVF would be a moderator of the relation between estimates of obesity and physical self-perceptions.

Methods

Participants

A sample of 104 (48 male, 56 female, 99% white) children from grades 4 and 5 (age range = 9-12 yrs, mean = 10.70 yrs) were recruited from an elementary school in a small rural community in Kentucky. Participants were recruited via packets sent home to parents through home-room teachers. This resulted in an acceptable response rate of approximate 55% of children, enrolled in grades 4 and 5. Children who returned signed consent forms were called from class in groups of 5 to the nurse's office

where 2 different methods commonly used for estimating obesity as well as a measure of cardiovascular fitness were collected by properly trained exercise physiologists and health educators. In addition, after providing informed assent, participants completed a questionnaire to measure self-perceptions. Table 1 presents the correlation matrix, including means and standard deviations, for all variables included in the analysis. All procedures were reviewed by an institutional review board, and were approved to meet all ethical guidelines concerning human subjects research.

Instruments and Physiological Measures

Self-Perception Profile for Children. The Self-Perception Profile for Children²⁹ (SPPC) is one of the most widely used instruments to measure self-perceptions of children. The SPPC is a 36-item scale that measures children's domain-specific perceptions of their competence, and assesses global perception of self-worth.³⁰ The SPPC contains 5 6-item subscales encompassing multiple facets of the self. For the current study, only scores from the Athletic Competence (AC), and Physical Appearance (PA) subscales were collected to obtain children's physical self-perceptions. Studies have shown the SPPC to have adequate internal consistency. Acceptable internal consistency has been reported for children in third to fifth grade with Cronbach's alpha of .80 for AC and .80 for PA.²⁹ With the current sample, Cronbach's alpha was .80 for AC and .83 for PA.

Body Mass Index (BMI) was calculated by dividing weight in kilograms by the square of height in meters (kg/m²). Height and weight was measured twice, using a Seca 225 Height Rod stadiometer, and rounded to the nearest 0.1 kg and cm, respectively.

Waist Circumference (WC) was collected as an estimate of central obesity. WC was rounded to the nearest 0.1 cm, was taken twice at the narrowest point of the waist using a Gulick tape measure. Both measurements were then averaged to create a final WC value.

Cardiovascular Fitness. Cardiovascular fitness (CVF) was assessed based on the results of a submaximal cardiovascular fitness test. A YMCA step test protocol was used to assess the cardiovascular fitness of participants.³¹ The step test protocol required the participant to step up and down on a 12 inch bench at a rate of 24 steps per

minute for 3 minutes. Heart rate was monitored continuously throughout the test using a Polar heart rate monitor. Heart rate was recorded immediately upon cessation of the test (t_0), and at 1 (t_1) and 2 minutes (t_2) posttest. The heart rate recorded immediately following the YMCA step test has been used by researchers in similar studies of children and has shown to be responsive to changes in fitness resulting from increases in physical activity.^{32,33}

Data Analysis

Two series of hierarchical regression analyses were conducted. In the first series, athletic competence was regressed on each obesity measure separately. In the second series, physical appearance was regressed on each obesity measure separately. Since the raw BMI score was used, which is unadjusted for age and gender, the relationship between gender and the 2 physical self-perception subscales was investigated to determine whether the effects of gender should be controlled for in the analyses. Because gender was not significantly related to athletic competence, it was not entered into the regression analyses predicting athletic competence. Thus, the obesity measure was entered in the first step as a risk factor; CVF was entered into the second step as a protective factor; and 2-way interactions between CVF and obesity measures were entered into the third step. For the second series of hierarchical regressions, gender was significantly related to physical appearance; therefore, it was entered in the first step of the regression. The obesity measure was entered into the second step. CVF was entered into the third step. Finally, 2-way interactions between CVF and obesity measures were entered into the fourth step.

Results

Athletic Competence

Results of the hierarchical regressions with BMI and waist circumference on athletic competence are displayed in Table 2. As expected, waist circumference significantly explained variance in athletic competence ($R^2 = .058$, $P < .05$); however, BMI was not significantly associated with athletic competence ($R^2 = .023$, $P = .063$). In the second

Table 1 Mean, Standard Deviation, and Correlations for BMI, Waist Circumference, Athletic Competence, Physical Appearance, and Cardiovascular Fitness

Variable	Mean	SD	1	2	3	4	5
1. BMI	20.8	4.1	1.0	.92**	-.11	-.26**	-.45**
2. Waist circumference	65.9	10.5		1.0	-.20	-.26**	-.46**
3. Athletic competence	17.1	3.1			1.0	.27**	.39**
4. Physical appearance	17.2	3.6				1.0	.25**
5. Cardiovascular fitness	1.5	.26					1.0

* $P < .05$; ** $P < .01$.

step, CVF accounted for a significant amount of variance in athletic competence over and above the relationship with obesity (BMI: $\Delta R^2 = .138$, $P < .01$; WC: $\Delta R^2 = .107$, $P < .01$). Finally, in the third step the 2-way interaction between fitness and obesity significantly explained variance over and above the independent association with both obesity and fitness (BMI: $\Delta R^2 = .032$, $P < .05$; WC: $\Delta R^2 = .035$, $P < .05$).

Following criteria established by Baron and Kenny (1986), 2 subsequent steps were performed to test if the association between the independent variable and the dependent variable varied as a function of the moderator. First, the moderating variable (ie, CVF) was changed from a continuous variable to a categorical variable. Specifically, CVF was split into 2 categories, 'low' and 'high,' using a median score cut-point. Second, regression analyses were used to examine the association between the obesity variable and athletic competence among individuals with low and high CVF scores. For both fitness groups, separate analyses were conducted regressing athletic competence on BMI and waist circumference (see Table 3). Results indicated that CVF moderated the relation between BMI and athletic competence, with higher BMI associated with greater athletic competence for the "high fitness" group. Conversely, CVF moderated the relation between waist circumference and athletic competence, such that higher waist circumference was associated with lower athletic competence for the "low fitness" group. Put another way, children in the *high*

fitness group with *higher* BMI scores were more likely to have *higher* athletic competence scores. On the other hand, children in the *low* fitness group with *higher* WC scores were more likely to have *lower* athletic competence scores.

Physical Appearance

Results of the hierarchical regression of BMI and waist circumference on physical appearance can be seen in Table 4. As expected, both BMI and waist circumference had significant negative relationships with physical appearance, over and above the relationship with gender (BMI: $\Delta R^2 = .040$, $P < .05$; WC: $\Delta R^2 = .055$, $P < .05$). In the third step, no significant variance was explained by CVF with either obesity measure (BMI: $\Delta R^2 = .016$, $P > .05$; WC: $\Delta R^2 = .010$, $P > .05$). In the fourth step, the 2-way interaction between obesity and fitness explained significant variance in physical appearance, controlling for gender and main effects (BMI: $\Delta R^2 = .036$, $P < .05$; WC: $\Delta R^2 = .033$, $P < .05$).

To demonstrate the nature of the interaction, we used CVF groups as described above. For both fitness groups, separate linear regressions were then conducted on physical appearance for both BMI and waist circumference (see Table 5). The results indicated that for both BMI and waist circumference, there were significant negative relationships between obesity and physical appearance for only the low fitness group.

Discussion

The main finding of this study is the moderating role of CVF between the relations of 2 different markers of obesity and children's physical self-perceptions. To our knowledge, this is the first study examining CVF's moderating role between these variables. A major strength of the current paper was the use of an objective measure of CVF. The consistency and scale of the moderating effect of fitness on the relationship between obesity and both physical appearance and athletic competence is compelling.

Concerning children's evaluations of their athletic competence, CVF moderated associations between obesity and athletic competence. CVF played different moderating roles depending on obesity measure. For BMI, there was a positive relationship between obesity and athletic competence, but only for those children who were more physically fit. That is, children who were larger and more physically fit had increased likelihood of better evaluations of their athletic abilities. Concerning waist circumference, the moderating effect of CVF revealed that children with larger waists had lower evaluations of athletic competence, but only among those who were less fit. In both instances, those with higher CVF had no

negative relationships between the obesity measure and athletic competence.

The results have clear implications for the engagement and maintenance of physical activity within the context of athletic activities. Late childhood is a developmental period in which significant declines in physical activity have been observed, especially in girls.⁴ While the focus of many childhood obesity interventions are to decrease BMI,^{34,35} the results of this study imply that an emphasis in increasing cardiovascular fitness may be more beneficial in maintaining positive attitudes about athletic abilities.

Consistent with previous literature, the results reported here indicate that estimates of obesity negatively relate to children's evaluations of their physical appearance,¹³⁻¹⁶ such that BMI and waist circumference were significant risk factors for poorer evaluations of their appearance. CVF consistently moderated associations between both measures of obesity and physical appearance. Specifically, for those who had higher CVF, BMI and waist circumference were no longer negatively associated with self-perceptions of physical appearance. In addition, for those with lower CVF, there was a negative association between obesity and self-perceptions of physical appearance. These results indicate that interventions

designed to increase and maintain physical activity and cardiovascular fitness may have the additional benefit of increasing children's satisfaction with their physical appearance.

The findings of the current study should be interpreted in light of its limitations. First, because the study design is not experimental or longitudinal, causality cannot be inferred. Another important aspect to be considered is the sample used in the study. Specifically, findings from this study may not be generalizable to nonrural community samples. Cultural norms and expectations in the rural community could be additional moderators of the relationship between obesity and self-perceptions that were not investigated in the current study. Similar explorations into the moderating effect of fitness level on the relation between obesity and physical self-perceptions, should sample children from several geographic locations.

The current results may have implications for both prevention and intervention programs. Previous research concerning CVF in adults indicates that small improvements in CVF, especially those with lower CVF, can have great impact on chronic disease morbidity and mortality.^{36–38} In the current study, low fitness was associated with greater risk of poor physical self-perceptions. It is plausible that the positive results found improving the CVF of adults with low CVF may also be found to have both physical and psychological benefits for children. Therefore, interventions that increase physical activity enough to have even small improvements in CVF may prove fruitful.

The study indicates that CVF may protect against obesity's association with psychological variables that could influence engagement in physical activity. The results of the investigation into the relationship between athletic competence and obesity indicate that understanding the distribution of fat may be more helpful in accurately understanding these relationships. Whenever possible, researchers concerned with the relations among obesity and psychological functioning should include CVF to better understand the relations between obesity and children's physical self-perceptions.

Acknowledgments

This project was supported by a grant from the Purchase Area Health Education Center (JBM, PI). The support of Loretta I. Maldaner (Director, Purchase AHEC) and the Crittenden County Elementary School were essential to completion of this project.
