This Article is brought to you for free and open access by the Animal Science Department at DigitalCommons@University of Nebraska - Lincoln. It has been accepted for inclusion in Nebraska Swine Reports by an authorized administrator of DigitalCommons@University of Nebraska - Lincoln.

most of the improvement of ADG and ADFI/ADG was achieved with 2,000 mg/kg Zn, with little or no further improvement as Zn concentration increased from 2,000 to 3,000 mg/kg. These results suggest pharmacological concentrations of Zn from ZnO are beneficial in the diets of SEW pigs. It was apparent the weight gain responses resulted primarily from increased voluntary feed intake. The mechanism for the feed intake response was not determined in this experiment, however, other reports suggest such improvements may be due to more healthy gut tissue and improved nutrient absorption.

Experiment 2.

In this experiment, no additive effect of Zn and carbadox was found (Table 4). Carbadox had no effect on ADG, ADFI and ADFI/ADG during Phase 1, Phase 2 or the overall experiment. This contrasts with results from previously reported studies. On the other hand, Zn increased ADFI in both the first and second phases and the overall experiment. Although the increase in ADG as Zn concentration increased was not statistically significant in this experiment, supplementation with 1,500 and 3,000 mg/kg of Zn increased ADG by 15 and 16 percent in phase 2, and by 12 and 14 percent in the overall experiment. The nonsignificant effect of Zn on ADG was probably because there were only two replications per treatment in this experiment. The results of the second experiment agree with the results of the first experiment. Feeding pharmacological concentrations of Zn stimulated voluntary feed intake and weight gain of pigs during the nursery phase.

The Effects of Dietary Feather Meal Concentration on Performance and Carcass Characteristics of Barrows

Kuo-Wei Ssu

Summary and Implication

An experiment was conducted to determine the effect of dietary feather meal level, as well as whether or not start weight influenced feather meal effects in growth performance and carcass traits of barrows. Dietary feather meal additions tended to decrease the final body weight variation of barrows. Barrows fed diets containing 20 percent feather meal from 80 pounds to slaughter had decreased average daily gain, average daily feed intake, digestible lysine intake, energy intake, daily lean gain and backfat depth. Barrows fed diets containing 10 percent feather meal from 190 pounds to slaughter had decreased average daily gain, average daily feed intake, digestible lysine intake, energy intake and backfat depth. The reduction in daily lean gain appears to be caused by decreased digestible lysine intake. Overall, feather meal can be used to reduce barrows feed intake, however, the dietary digestible lysine content should be adjusted.

Introduction

As more producers adopt all-in-all-out (AIAO) systems, the growth potential difference between barrows and gilts becomes a concern. Typically, barrows eat more feed, grow faster and reach market weight 10 to 14 days before littermate gilts. Because

barrows and gilts have similar protein growth potential in the finishing phase, barrows have fatter carcasses than gilts at the same live weight. Producers may be able to improve profitability if barrows growth rate can be modified to be similar to that of gilts. Improving carcass leanness of barrows is another potential profit opportunity. The greater backfat for barrows compared to gilts results in a lower price because the market systems use backfat as a predictor of carcass lean. Research has demonstrated that feather meal (a high-protein, low energy feed ingredient) reduces feed intake in finishing pigs. This article describes a experiment conducted to examine the optimum level and timing of dietary feather meal additions to barrow diets. The overall objective was to slow down the growth rate and to improve the carcass leanness of barrows.

Procedures

A pool of 224 crossbred, high lean gain potential feeder pigs (196 barrows and 28 gilts) were purchased from a single source. At arrival, all pigs were weighed, eartagged and assigned randomly to experimental treatments on the basis of four weight outcome groups. Within outcome group, barrows were randomly assigned to one of seven treatment groups and gilts were assigned to control gilt group.

The experiment was conducted at the University of Nebraska Haskell Agriculture Laboratory at Concord. The facility is a fully slatted, double-wide, naturally ventilated barn with fresh water under-slat flushing for manure

(Continued on next page)

removal. One nipple drinker and two feeder spaces were provided in each 7 ft x 8 ft pen with a total of four pens per treatment combination. There were seven pigs in each pen with floor space of 8 ft²/pig.

The control barrows (**CB**) and gilts (**CG**) were fed diets containing no feather meal from purchase to slaughter (Tables 1, 2 and 3). Treatment groups were two levels of dietary feather meal (**FM**, 10 and 20 percent), fed from three different starting weights (**SW**, 80, 135 and 190 pounds). Barrows were fed the same corn-soybean meal diets as the CB group before they reached the assigned starting weights, 80, 135 and 190 pounds. The CB group served as a benchmark to evaluate treatment effects. The CG group served as a benchmark to evaluate the performance of barrows.

Diets were formulated to contain similar metabolizable energy densities and the digestible lysine (the first limiting amino acid) concentrations used were derived from the Nebraska and South Dakota Swine Nutrition Guide. All pigs were fed a common corn-soybean meal diet formulated to contain 1 percent lysine from arrival until 80 pounds. Diets were switched on the week pigs weighed 80, 135 and 190 pounds. Pens of pigs were slaughtered the week the average pen weight was 240 pounds or greater.

Carcass lean was measured on individual pigs at slaughter using total body electrical conductivity (TOBEC) at SiouxPreme Packing Co., Sioux Center, Iowa. Backfat depth was measured at the tenth rib 2 inches off the midline by Renco LeanMeter five days prior to slaughter. Lean percentage was calculated on a 5 percent fat basis.

Results and Discussion

The coefficient of variation of final weights is an expression of the body weight variation within each pen at time of slaughter. Barrows fed 10 percent FM from 190 pounds and 20 percent FM from 135 pounds tended ($P < .1$) to have smaller coefficient of variations at the end of the experiment

($P < .05$) average daily gains than control harrows and their average daily gain was similar to CG. The control gilts had the lowest average feed intake among all treatment groups, and harrows fed 20 percent FM from 80 pounds had similar feed intake as CG. Barrows fed 10 percent FM from

190 pounds and 20 percent FM from 80 pounds consumed less ($P < .05$) feed than control barrows. Feed efficiency was not affected by dietary FM additions.

The daily digestible lysine intake of CG and CB were greater ($P < .05$) than harrows fed 10 percent FM from

190 pounds and 20 percent FM from 80 pounds. Barrows fed 10 percent FM from 190 pounds and 20 percent FM from 80 pounds had less ($P < .05$) daily metabolizable energy intake than the control harrows, with energy consumption similar to the control gilts. The control barrows and control gilts had similar daily lean gains. Twenty percent dietary FM fed from 80 pounds reduced ($P < .05$) the daily lean gain of harrows. Barrows fed 20 percent FM from 80 pounds had similar average daily gains and average daily feed intakes similar to control gilts. Pigs in this group needed seven additional days to reach market weight when compared to control harrows.

The control gilts had the least backfat and the control harrows had the greatest backfat depth among treatment groups. Barrows fed 10 percent FM from 190 pounds and 20 percent FM from 80 and 190 pounds had reduced ($P < .05$) backfat depth compared with control harrows. There was a significant effect of SW ($P < .05$) on backfat depth, suggesting that the timing of FM additions is more important than dietary concentration to reduce barrows backfat. In this study, barrows

fed dietary FM (10 and 20 percent) from 190 pounds had a significant backfat reduction. None of the FM treatments reduced the backfat to the same depth as control gilts.

We acknowledge the lean percentage of these high lean gain pigs appears low. We checked the equation used in conjunction with TOBEC readings, and discussed the results with the packer, but did not find any reason to explain this observation. The lean percentage values in Table 4 are based on 5 percent added fat. They are surprisingly low, given the backfat measurements and visual appraisal at time of slaughter. The SW tended ($P = .07$) to affect the lean percentage. The control gilts had the highest lean percentage. Dietary FM did not improve the lean percentage of barrows to equal that of the control gilts in this study.

Barrows fed 20 percent FM from

80 pounds had similar average daily gain, average daily feed intake and energy intake as control gilts, but the daily lean gain and lean percentage were less than control gilts. An explanation for this situation is a reduction in daily digestible lysine intake. The reduction of digestible lysine intake may have limited the daily lean gain of the barrows. When compared to the barrows fed 10 percent FM from 190 pounds, the barrows fed 20 percent FM from 80 pounds had numerically more backfat and less carcass lean. This indicates that feeding 20 percent FM from 80 pounds may help manipulate the growth performance of barrows to resemble that of gilts, but the lean growth and carcass lean percentage will decrease if the dietary digestible lysine intake is not adjusted. These results suggest that feeding 10 percent FM during the late finishing phase and

adjusting dietary digestible lysine concentration to meet the maximum lean growth requirement may slow daily gain and improve carcass leanness of barrows.

Conclusion

Feather meal reduces barrows average daily gain and average daily feed intake. The dietary digestible lysine content should be adjusted to meet the maximum lean growth if FM is used to slow growth rate and improve carcass leanness of barrows.

Defining Swine Nutrient Requirements and Allowances—What do the Numbers Mean?

Phillip S. Miller
Austin J. Lewis
Duane E. Reese
Michael C. Brumm¹

Summary and Implications

Defining nutrient requirements or allowances is the first, and conceivably most important step, in developing a nutrition program for growing-finishing pigs. Understanding the terminology and underlying principles used to define nutrient requirements and allowances for pigs will help producers better evaluate their nutrition programs. This information will also enable producers to interface production outputs (e.g., growth rate and carcass data) to published nutrient requirement and allowance programs,

such as The National Research Council, Nutrient Requirements of Swine, 1998. As these and other approaches describing nutrient requirements for pigs develop, producers need a better and more complete understanding of growth biology in order to help them accurately determine the nutritional needs of their pigs. Because of the diminishing-return response of growth and biological traits to nutrient intake or concentration, the added costs associated with increasing nutrient densities at or near the requirement must be carefully considered.

Introduction

Nutrient requirements/allowances are determined based on the response of biological or growth criteria to vary-

ing intakes or concentrations. These criteria vary according to the physiological state of the pig (i.e., growth, pregnancy or lactation) and the level of production (e.g., 1.5 versus 2.2 pounds weight gain/day). The objectives of this article are to review the general processes for development of nutrient requirements and allowances, to illustrate the differences between a nutrient requirement and allowance, and to discuss how maximizing a biological response may not maximize economic returns.

Performance Criteria

Nutrient requirements are rarely based on a single research experiment but most often derived from a variety of experiments. Conditions vary among
