Abstract
In the atmosphere, a well-known and conventional pathway toward the formation of ammonium sulfate is through the neutralization of sulfuric acid with ammonia (NH3) in water droplets. Here, we present direct ab initio molecular dynamics simulation evidence of the formation of ammonium bisulfate (NH4HSO4) from the hydrated NH3 and SO3 molecules in a water trimer as well as on the surface of a water droplet. This reaction suggests a new mechanism for the formation of ammonium sulfate in the atmosphere, especially when the concentration of NH3 is high (e.g., ~10 μg m−3) in the air. Contrary to the water monomer and dimer, the water trimer enables near-barrierless proton transfer via the formation of a unique loop structure around the reaction center. The formation of the loop structure promotes the splitting of a water molecule in the proton-transfer center, resulting in the generation of a NH3+/HSO4− ion pair. The loop-structure promoted proton-transfer mechanism is expected to be ubiquitous on the surface of cloud droplets with adsorbed NH3 and SO3 molecules and, thus, may play an important role in the nucleation of aerosol particles (e.g., fine particles PM2.5) in water droplets.

Atmospheric aerosols have become a central topic in the environmental and atmospheric science due to their influence on the biosphere,1 climate,2–6 and public health.7,8 Many experimental studies have shown that sulfate salts (ammonium sulfate in particular) are one of the main constituents in aerosols (e.g., fine particles PM2.5) and play a key role in the formation of sulfur-containing aerosols by acting as condensation nuclei.9–14 Investigation of the formation mechanism of ammonium sulfates in the atmosphere is both timely and important to the understanding of the nucleation and growth of aerosol particles, thereby may lead to better science-based solutions in resolving the severe haze problems (such as those occurred recently in the winter season of eastern China).

In the atmosphere, ammonium sulfate is generally believed to be formed via the neutralization of sulfuric acid (H2SO4) with ammonia (NH3) molecules.15 Although the sulfuric acid formation from the bimolecular reaction between SO3 and H2O entails a high activation energy barrier (28–32 kcal/mol),16–18 recent studies have shown that the reaction energetics can be significantly influenced by the participation of four or more water molecules or other atmospheric molecules such as the HO2 radical and formic acid.19,20 In a highly polluted atmosphere, the concentration of NH3 may rise to 10 μg·m−3 (~3.5 × 1017·m−3), much higher than that of the HO2 radical and formic acid and may even be comparable with that of water monomers (~7.73 × 1017·m−3 at 100% relative humidity and 298.15 K).21 This suggests that ammonia molecules can play a more direct role in the formation of ammonium sulfate. An early study has shown that ammonia can act as a catalyst to promote the formation of sulfuric acid by lowering the energy barrier to ~3.80 kcal/mol, but without the formation of NH4+.22 Another possible mechanism23 considered involves the barrierless formation of a donor–acceptor NH3+/SO42− complex, which has a binding energy of ~20 kcal/mol24–27 much higher than that of the H2O·SO3 complex (~7.9 kcal/mol).16 Though the NH3·SO4 complex can also lead to sulfamic acid,26,28 the reaction is endothermic with a high barrier of ~16.13 kcal/mol.22 Although recent experimental studies have shown the promoting role of NH3 in the nucleation of aerosol particles, a detailed chemical mechanism for the formation of ammonium sulfate from NH3 and SO3 is still largely unknown.

Here, we show direct ab initio molecular dynamics (AIMD) simulation evidence of the near-barrierless formation of ammonium bisulfate (NH4HSO4) from the hydrated NH3 and SO3 molecules. In this new chemical mechanism, a loop structure is identified to play a key role in promoting the water-mediated proton transfer that leads to the formation of NH4HSO4. Observation of the near-barrierless formation of ammonium bisulfate (NH4HSO4) in the water trimer as well as on surface of a water droplet suggests an alternative dominant channel toward the formation of ammonium sulfate, a major component of aerosol particles in the water droplets.

Born–Oppenheimer AIMD simulation is performed on the basis of density functional theory (DFT) methods as implemented in the CP2K code.29 The exchange and correlation interactions of electrons are treated with the Becke–Lee–Yang–Parr (BLYP) functional30,31 and the Grimme’s dispersion correction method is applied to account for the weak dispersion interaction.32 A double-ζ Gaussian basis set combined with an auxiliary basis set33 and the Goedecker–Teter–Hutter (GTH) norm-conserved
pseudopotentials are adopted to treat the valence electrons and the core electrons, respectively. An energy cutoff of 280 Ry is set for the plane wave basis set and 40 Ry for the Gaussian basis set. A supercell (20 × 20 × 20 Å³) with periodic boundary conditions is selected for the (NH₄)₃(SO₃)(H₂O)ₙ (n = 1−3) systems, which is large enough to neglect interaction between the neighboring replica. For the water droplet system, a relatively large supercell with size (35 × 35 × 35 Å³) is used. The water droplet with 192 water molecules is carved out from the supercell of pre-equilibrated bulk water at 300 K and re-equilibrated at 300 K for ~6 ps. Upon the adsorption of a NH₃ and a SO₃ molecule onto the surface of the water droplet, the structure is further optimized at DFT level of theory before the AIMD simulations. All the AIMD simulations are performed in the constant volume and temperature ensemble with the temperature controlled at 300 K. The climbing image nudged-elastic-band (CI-NEB) method is used to locate the transition state. In addition, the geometries of reactant and product states are also optimized at the MP2/6-311++G(d,p) level of theory, while the transition state is further confirmed via frequency analysis at the MP2 level of theory, using the Gaussian 09 software. These separated MP2 computations allow confirmation of the activation energy barrier for each reaction.

First, we compute the energy barrier to the formation of NH₄HSO₄ from NH₃ and SO₃ associated with one or two water molecules, using the CI-NEB method. For the water monomer system, as shown in Figure 1, the splitting of the water molecule requires to overcome an energy barrier of ~3.78 kcal/mol (3.96 kcal/mol at the MP2/6-311++G(d,p) level), consistent with a previous study. Upon splitting of the water molecule, both OH⁻ ion and the proton bind with the SO₃ molecule, leading to the exclusive formation of H₂SO₄⁻. In contrast, the inclusion of an extra water molecule in the dimer system can promote the proton transfer from the water molecule to the NH₃ molecule and stabilize the NH₄⁺ due to the added hydration effect. As shown in Figure 1, the proton of one water molecule that is near the SO₃ shifts toward the other water molecule that interacts directly with NH₃. Meanwhile, the proton of the other water molecule shifts toward NH₃, leading to the formation of NH₄⁺, while the remaining OH⁻ ion binds with the SO₃ to form HSO₄⁻. Overall the water molecule near NH₃ acts as a proton transporter by accepting the proton from one source and delivering it to another molecule. Such a reaction mechanism can be viewed as a water-mediated proton-transfer mechanism as previously reported, and this mechanism enables the formation of NH₄⁺/HSO₄⁻ ion pair in the dimer system with a slightly lower barrier of ~3.30 kcal/mol (3.80 kcal/mol at the MP2/6-311++G(d,p) level). However, during the AIMD simulations of both water monomer and dimer systems, neither the NH₄⁺/HSO₄⁻ ion pair nor NH₃/H₂SO₃ complex is observed due largely to the notable energy barriers for the formation reactions (see Figures S1 and S2, and Movies S1 and S2).

In the atmosphere, although the population of the water trimers is about 1 order of magnitude less than that of the water dimers, the water trimer may still play a key role in certain chemical reactions if the hydration effect becomes increasingly important with increasing the size of water clusters. This is indeed the case for the formation of ammonium bisulfate. Unlike the water monomer and dimer systems, the formation of NH₄HSO₄ can be directly observed during the AIMD simulation with the water trimer system (Movie S3). As shown in Figure 2a, the SO₃ molecule is fully hydrated by the water trimer (set as the initial configuration) through the donor–acceptor interaction between the π orbital of SO₃ and the p orbital of atomic O, while the NH₃ molecule only interacts with the water molecule via the N–H bond. The NH₃/H₂SO₃ complex is observed only when the proton interacts with the SO₃ molecule via the N–H bond, forming a hydrogen bond (H-bond). Initially (~2.47 ps) the N–H bond and S–O lengths only fluctuate around 1.80 and 2.10 Å, respectively, without showing any bond formation. At ~2.47 ps, a shift of the dangling water molecule (the circled molecule in Figure 2a) toward the SO₃ molecule shorts the O₃−H₃ length to ~1.60 Å and reduces the H₂O−O angle to <30° (see black line in Figure 2b and Figure S3), leading to the formation of an

(b) The time evolution of the N–H₁, S–O₁, O₁–H₂, O₂–H₁, O₂–H₂, and O₃–H₃ lengths in the course of the AIMD simulation. The inset illustrates the loop structure formed prior to the formation of the NH₄⁺/HSO₄⁻ ion pair.
H-bond between the dangling water molecule and the SO$_3$. This leads to a loop structure involving the water trimer and SO$_3$, as shown in the snapshot at 2.47 ps (see also the inset in Figure 2b). Upon the formation of the loop structure, the O$_3$−H$_2$ and O$_3$−H$_3$ lengths are elongated to ~1.75 and 2.09 Å, respectively, suggesting the breakage of O−H bonds. On the other hand, the N−H$_2$ and O$_1$−H$_3$ lengths decrease to ~1.04 and 0.96 Å, respectively, suggesting the formation of new N−H and O−H bonds. This bond length evolution involves transfer of two protons, resulting in the formation of NH$_4^+$ and regeneration of a water molecule (Figure 2a). Meanwhile, the remaining OH$_2$ group quickly binds with SO$_3$, giving rise to HSO$_4^−$. After the NH$_4^+/HSO_4^-$ ion pair is formed with two water molecules (Movie S3), no significant change in the N−H$_2$ and the S−O$_2$ bonds is seen, suggesting the unlikelihood of the reverse reaction. Note that the water trimer we considered here entails a linear structure. The formation of the NH$_4^+/HSO_4^-$ ion pair is also observed in an independent AIMD simulation with a loop-shaped water trimer as the initial structure. With the latter, the reaction proceeds even faster (Movie S4). The direct observation of the formation of the NH$_4^+/HSO_4^-$ ion pair with the water trimer indicates the reaction is nearly barrierless. This is also confirmed from our independent reaction path computation using the CI-NEB method (see Figure 1). The computed energy barrier is merely ~0.08 kcal/mol (less than the factor $k_BT$, where the temperature $T = 300$ K and $k_B$ is the Boltzmann constant).

Overall, the formation mechanism of the NH$_4^+/HSO_4^-$ ion pair in the water trimer system is quite similar to that for the dimer system, but involves a very low barrier. As shown in the inset of Figure 2b, the two water molecules (in blue) act as the reaction center where the water molecule having O$_2$ plays the role of proton transporter, i.e., to accept and deliver the proton. The extremely low barrier is largely due to the formation of a loop structure involving the third water molecule. Moreover, the presence of the third water molecule results in a stronger exothermic reaction (−10.12 kcal/mol), thereby further enhancing the stability of NH$_4$HSO$_3$. We have also simulated the reaction of NH$_3$ and SO$_3$ in a water tetramer system. As shown in Figure S4, no reaction barrier is seen during the formation of NH$_4^+/HSO_4^-$ ion pair, while the same reaction mechanism is observed as in the trimer system. In the AIMD simulation, the proton transfer occurs at ~0.44 ps (Movie S5), suggesting relatively faster formation of NH$_4^+/HSO_4^-$ ion pair.

Previous studies suggest that water droplets in the upper troposphere (>2 km) may play an important role in the atmospheric chemistry. Particularly, the water−air interface has been suggested as the key area for many important chemical processes, such as the ionization of N$_2$O$_4$, the acid formation from sulfur, nitrogen oxide and organic compounds, and the Cl$_2$ formation from the Cl$^-$ oxidation, among others. We have performed an independent AIMD simulation of the formation of the NH$_4^+/HSO_4^-$ ion pair on the surface of a water droplet upon the adsorption of a NH$_3$ and a SO$_3$. A loop-structure promoted proton-transfer mechanism is observed as in the water trimer and tetramer systems. As shown in the Figure S5, prior to the reaction, the N−S bond length varies from ~4.00 to 11.00 Å, indicating no direct interaction between NH$_3$ and SO$_3$. Figure 3a, SO$_3$ forms a cyclic structure with four water molecules at ~4.96 ps. Notably, such a cyclic structure differs from the loop structure obtained in the water trimer system. As shown in Figure 3b, the O$_3$−H$_2$ length is shortened to ~2.10 Å (marked by the gray arrow), whereas the O$_2$−H$_3$ length still maintains to be ~2.10 Å, indicating the formation of two H-bonds with a single oxygen atom not in the loop structure. Beyond 7.42 ps (marked by the red arrow), the O$_2$−H$_3$ length increases to ~3.20 Å, accompanied by the decrease of the O$_3$−H$_2$ length from 3.50 to ~2.10 Å due to the flipping over of the circled water molecule shown in Figure 3a. The flip transforms the cyclic structure into a loop structure, as observed in the water trimer system where only one H-bond is formed with each oxygen atom. Such behavior is also suggested based on the analysis of the orientation variation of water molecules (Figure S6). Again, the formation of the loop structure stimulates the proton transfer among the water and NH$_3$ molecules and results in the breaking of the O$_3$−H$_3$ and the O$_2$−H$_3$ bonds (Figure S5) and the formation of the O$_3$−H$_2$ bond (Figure 3b and Movie S6). Concurrently, the N−H$_2$ and the S−O$_2$ lengths are shortened to ~1.07 and 1.68 Å, respectively, indicating the formation of the NH$_4^+$ and ions. Also, as shown in the inset of Figure 3b, the proton-transfer mediated by the water molecule occurs in the reaction center, which involves a water dimer (in blue) and a NH$_3$ molecule. The other two water molecules (in red) act as the “bridge” to form the loop structure. Hence, both the water trimer and the water-droplet systems demonstrate the same mechanism for the formation of the NH$_4^+$/HSO$_4^-$ ion pair.

In conclusion, we have provided direct AIMD simulation evidence for the formation of NH$_4$HSO$_3$ from the separately hydrated NH$_3$ and SO$_3$ molecules in a water trimer and on the surface of a water droplet. In both systems, direct interaction (adduct) of NH$_3$ and SO$_3$ is not observed, whereas the NH$_4^+$/HSO$_4^-$ ion pair is formed instead, following a loop-promoted proton-transfer mechanism. In this mechanism, two water
molecules that directly interact with NH₃ and SO₂ serve as the reaction center, while the third water molecule acts as a “bridge” to connect the reaction center with the SO₂ molecule to form a loop structure. The proton transfer in the reaction center is akin to that in the dimer system where one water molecule acts as a proton transporter. Our computations show that the loop structure formed in the water trimer and water-droplet systems can greatly promote the proton transfer in the reaction center, leading to a near-barrierless reaction. The AIMD simulation provides atomic-level mechanistic insight into the formation of ammonium bisulfate that can be a major precursor for the formation of ammonium sulfate. The latter is known to be a major component in the liquid droplet of aerosols, e.g., the PM$_{2.5}$ microparticles.
