Density-Gradient Centrifugation: Non-Ideal Sedimentation and the Interaction of Major and Minor Components

Abstract. A small amount of southern bean mosaic virus was contained in a narrow zone after density-gradient centrifugation, but in a much wider zone after centrifugation with a large amount of a second virus. Zone-spreading of a major component by non-ideal sedimentation in density-gradient centrifugation can cause zone spreading of a minor component that the major component overlaps.

The width of a zone of virus or protein after sucrose density-gradient centrifugation increases as the amount in the zone increases (1). The amount of virus or protein in a zone of a given width is only a few percent of that which would be present if the negative density-gradient which is due to the virus or protein concentration gradient were equal to the positive density gradient due to the sucrose concentration gradient. Brakke (1) postulated that the increase in zone width as the amount of virus or protein in-
increased was due to non-ideal sedimentation, which became increasingly important as the concentration of virus or protein increased. He further postulated that the mechanism of non-ideal sedimentation was the sedimentation of volume elements containing such excess virus or protein particles as were expected from statistical or fluctuation theory. If this mechanism of non-ideal sedimentation is correct, then the spreading of a component present in high concentration should result in the spreading of a component present in low concentration if the two zones overlap. The present experiments were designed to test this hypothesis.

Radioactive southern bean mosaic virus (SBMV-C^14) (AC No. 17) (2) was prepared by growing infected Bountiful bean plants (Phaseolus vulgaris L.) in an atmosphere containing C^14O_2. The SBMV-C^14 was purified by differential centrifugation after heating the extract from the infected plants for 15 minutes at 50°C to denature the normal plant proteins. Tobacco mosaic virus (TMV) (AC No. 2) was purified by the method of Boedtker and Simmons (3). Brome mosaic virus (BMV) (AC No. 66) was purified by differential centrifugation of a frozen extract of diseased barley, Hordeum vulgare L. Moore.

The zone width of SBMV-C^14 was determined after density-gradient centrifugation of a small amount of SBMV-C^14 by itself or in the presence of a large amount of either BMV or TMV. Gradient columns were prepared by layering 4.77 ml of 0.01M phosphate buffer, pH 6.8, containing 100, 200, 300, and 400 mg of sucrose per milliliter, respectively, in the centrifuge tube. The sucrose column was allowed to stand overnight, 2 ml of virus solution was then floated on it, and it was centrifuged for 3 hours at 23,000 rev/min at 5°C (SW25.1 rotor of the Spinco model L ultracentrifuge) (4).

The centrifuged gradient columns were examined to obtain a recording of absorbancy at 253.6 nm (5) at all depths (ISCO Density-Gradient Fractionator) and consecutive fractions were collected (5). 0.2 ml at depths where preliminary experiments had indicated that most of the radioactivity would be found and larger samples at other depths. These samples were diluted with four volumes of water and three 0.2-ml portions of each were transferred to glass planchets containing lens paper. The weights of material on each planchet were obtained in order to correct for self-absorption.

Because of only slight differences in total amounts of sucrose in the samples, no self-absorption correction was necessary in presenting data (see Fig. 1) for radioactive zones. In order to estimate recovery of viruses on the gradient columns, it was necessary to correct for differences in self-absorption between the original samples of radioactive virus and each radioactive fraction. High concentrations of sucrose in the samples resulted in erratic counts apparently caused by the geometric effects of sucrose crystallization. The above fourfold dilution eliminated this source of poor reproducibility.

Each gradient column of the experiment whose results are shown in Fig. 1 contained 0.3 mg (42,000 count/min) of SBMV-C^14. In addition, the second column contained 40 mg of TMV and the third, 20 mg of BMV. The BMV has S_20,w of 865 (5); SBMV, of 1155 (6) and TMV, of 1875 (8). These three viruses are well separated by density-gradient centrifugation of small amounts. However, the zones of large amounts of BMV and TMV as used here are wide and overlap the SBMV zone.

Apparantly the SBMV-C^14 zone was much wider in the presence of large amounts of the other two viruses than

Fig. 1. Absorbancy and radioactivity at different depths after density-gradient centrifugation of 0.3 mg of SBMV-C^14 by itself, or in the presence of 40 mg of TMV or 20 mg of BMV. A cell with a 2-mm light path was used and absorbancies were multiplied by 5 to give values for a 1-cm light path. The absorbancy in the scanning pattern of SBMV-C^14 alone was expanded electronically to increase sensitivity. The recovery of radioactivity was 106 percent for the column with SBMV only, 92 percent for SBMV plus TMV, and 94 percent for SBMV plus BMV, after correction for differences in self-absorption between the original sample and samples obtained from the sucrose-gradient column.
in their absence. Furthermore, the
peak concentration of the SMBV
\((-C_{14})\) was always lower in the tube
in the presence of BMV than when
SBMV\((C_{14})\) was sedimented by itself
or with TMV. These data show that
non-ideal sedimentation of a ma-
jor component during density-gradi-
ent centrifugation can result in widen-
ing of the zone of a minor component
that it overlaps and in a different ap-
parent sedimentation rate of the minor
component.

Sucrose density-gradient centrifuga-
tion is often used to determine the
size of particles carrying a certain bi-
ological or chemical activity. Results in
such experiments are obtained by de-
termining the activity, for example, vi-
rus infectivity, enzymatic activity, or
a radioactive tracer, at various depths
in the column after centrifugation. Vi-
ruses and proteins form wide zones at
high concentrations (I). Apparently
non-ideal sedimentation, which causes
the zone spreading, is pronounced at
concentrations higher than 2 to 3
mg/ml and the sedimenting material
spreads until the maximum concen-
tration does not exceed 2 to 3 mg/ml.
Our studies show that it is not the
concentration of an individual com-
ponent that determines the amount of
non-ideal sedimentation and zone
spreading, but rather the total concen-
tration of materials sedimenting to-
gether. If this concentration is high,
and followed by the determination of
enzymatic or other activity, a par-
ticle present in low concentration
will give neither a true indication of
its homogeneity nor an accurate value
of its sedimentation rate. For good res-
olution (I), the amount of sediment-
ing material should be less than 1 mg
for the 2.5- by 7.6-cm tube of the SW
25 rotor of the Spinco model L.
