The thickness dependence of fullerene on CH$_3$NH$_3$PbI$_3$ perovskite film surface has been investigated by using ultraviolet photoemission spectroscopy (UPS), X-ray photoemission spectroscopy (XPS), and inverse photoemission spectroscopy (IPES). The lowest unoccupied molecular orbital and highest occupied molecular orbital (HOMO) can be observed directly with IPES and UPS. It is observed that the HOMO level in fullerene shifts to lower binding energy. The XPS results show a strong initial shift of core levels to lower binding energy in the perovskite, which indicates that electrons transfer from the perovskite film to fullerene molecules. Further deposition of fullerene forms C$_{60}$ solid, accompanied by the reduction of the electron transfer. The strongest electron transfer happened at 1/4 monolayer of fullerene. © 2015 AIP Publishing LLC.

Methylammonium lead trihalides have attracted great attention as candidates for the next generation solar cells as the power conversion efficiency has exceeded 16%. The advantages of these materials include being solution-processable, low cost of large carrier mobility and long carrier lifetime, and abundance in nature. The solution-processibility makes it high possibility for low energy fabrication of large area photovoltaic platforms. A great amount of evidence shows that the working mechanism of the perovskite planar heterojunction (PHJ) solar cells is similar to other inorganic polycrystalline solar cells such as silicon and cadmium telluride (CdTe) materials. One of the most important strategies to optimize the device efficiency for those polycrystalline solar cells is to minimize the charge recombination at the surfaces and grain boundaries. Fullerene-based materials, such as fullerene (C$_{60}$) and (6,6)-phenyl-C$_{61}$-butyric acid methyl ester (PCBM), have been the favored acceptor component in organic photovoltaic devices and recently applied in perovskite PHJ solar cells. Shao et al. showed that the fullerene layers, which were designed as electron acceptors, might effectively passivate the charge trap states at both CH$_3$NH$_3$PbI$_3$ perovskite film surfaces and grain boundaries, as the fullerene eliminated the photocurrent hysteresis and doubled the efficiency of CH$_3$NH$_3$PbI$_3$ solar cells. Given the significance of the observation, it is imperative to investigate the interface formation and energetics in order to understand the underlining physical mechanisms.

In this paper, we report our investigation on the evolution of the electronic structure and the energy level alignment at the C$_{60}$/perovskite interface using ultraviolet photoemission spectroscopy (UPS), x-ray photoemission spectroscopy (XPS), and inverse photoemission spectroscopy (IPES). We monitored the changes of the valence electronic structures, including the highest occupied molecular orbital (HOMO), the lowest unoccupied molecular orbital (LUMO), and the vacuum level (VL), as C$_{60}$ was successively deposited layer by layer on perovskite film coated on indium tin oxide (ITO) substrate. We also monitor the core levels change by XPS. These investigations provide important insight to the improvement of the perovskite solar cells by fullerene layers.

UPS measurements were performed using a modified VG ESCA Lab system, an ultrahigh vacuum (UHV) system equipped with a He discharge lamp. The UHV system consists of three interconnecting chambers, a spectrometer chamber, an in-situ oxygen plasma (OP) treatment chamber, and an evaporation chamber with a precision air leak valve. The base pressure of the spectrometer chamber is typically 8 × 10$^{-11}$ Torr. The base pressure of the evaporation chamber is typically 1 × 10$^{-6}$ Torr. The UPS spectra were recorded by using unfiltered He I (21.2 eV) excitation as the excitation source with the sample biased at −5.00 V to observe the low-energy secondary cutoff. The UV light spot size on the sample is about 1 mm in diameter. The XPS studies were performed with a MgK$_{\alpha}$ x-ray source (1253.6 eV). The typical instrumental resolution for UPS and XPS measurements is 0.1 and 1.4 eV, respectively. The IPES spectra were taken with a custom-made spectrometer composed of a commercial Kimball Physics ELG-2 electron gun and a band pass photon detector prepared according to an existing design. The combined resolution (electron + photon) of the IPES spectrometer was determined to be ∼0.6 eV from the Fermi edge of an evaporated Au film. All depositions were done at room temperature and monitored with a quartz crystal microbalance. For the film fabrication, PbI$_2$ and CH$_3$NH$_3$I (MAI) were first dissolved in dimethylformamide (DMF) and 2-propanol, respectively, as precursor solutions. The precursors were then spun onto poly(3,4-ethylenedioxythiophene) poly(styrenesulphonate) (PEDOT:PSS) covered...
ITO glass with a PbI₂ layer underneath an MAI layer. A supersaturated hot solution of PbI₂ was used for quick drying to obtain a pin-hole free and conformal PbI₂ layer on the PEDOT:PSS surface. Since PbI₂ has relatively low solubility in 2-propanol, the spin coating of MAI solution did not wash off the PbI₂. The bilayer film was then annealed at a temperature of 100 °C for 120 min.

Thermal admittance spectroscopy (TAS) analysis was used to quantize the reduction of trap states in perovskite films by the passivation of C₆₀ and PCBM. TAS is a well-established technique for charactering both shallow and deep defect levels. TAS has been widely applied in understanding defects in thin film solar cells¹⁷ and organic solar cells.¹⁸ Shao et al demonstrated that there was a relatively large density of defect states on the order of 1 × 10¹⁷ to 1 × 10¹⁹ m⁻³ in the devices without any fullerene passivation, which indicated the large hysteresis of photocurrents observed.²³ The trap density of state (tDOS) with an energy level above 0.40 eV decreased by one order of magnitude just after the spin coating of C₆₀ on the perovskite films even without thermal annealing. Especially with the energy level above 0.5 eV, the tDOS decreased for nearly two orders. The remarkable decrease of the tDOS was consistent with the decreased photocurrent hysteresis, indicating the effective passivation of charge traps in perovskite by C₆₀. But the charge transfer situation is not clear at the interface of C₆₀ and perovskite. In order to investigate the charge transfer process between the C₆₀ and perovskite, we carried out the layer by layer research of C₆₀ on perovskite.

In Figure 1, we show the UPS and IPES spectrum of the perovskite film. The UPS spectrum was taken first and then the IPES spectrum was recorded on the same film subsequently. The origin in Figure 1 is the Fermi level, which was calibrated by UPS and IPES on the Au/Si substrates. The spectra on the left side of the Fermi level are the valence bands from UPS, while the spectra on the right side are the conduction bands from IPES. For the pristine perovskite film, the valence band (VB) feature is very clear and the valence band maximum (VBM) is 0.76 eV. The conduction band minimum (CBM) is 0.90 eV, which is consistent with the previous reports.³,¹⁹ We define the onset as the extrapolation of the leading edge (closer to the Fermi level) in the spectrum. The results are an injection energy gap of about 1.66 eV, interestingly very close to the previous report.¹⁹,²⁰

In Figure 2, the evolution of UPS spectra due to different C₆₀ thickness is presented. C₆₀ (99.99% purity) was purchased from SES Research and thermally deposited on the perovskite film. Figure 2(a) shows the cutoff changes of the UPS spectra, which reflect the vacuum-level change of the samples. It is very impressive that a very thin layer of C₆₀ film (as low as 2 Å) can significantly change the vacuum level, thus the sample work function. The pristine perovskite film had a WF of 4.73 eV, which is consistent with the previous reports.²¹ With the C₆₀ thickness increasing, the WF shifted to lower binding energy, which means higher WF. The WF was 6.15 eV when the C₆₀ thickness was at 2 Å. The change slowed down and finally saturated when the C₆₀ thickness reached to 128 Å. In Figure 2(b), it shows the HOMO region of the UPS spectra of the same films. It can be observed that with the C₆₀ thickness increasing, the HOMO shift followed the cutoff changes, implying that the C₆₀ molecule does not undergo significant chemical modification. No new state emerges from the gap with the C₆₀ thickness increasing. The shifts of the energy levels were due to the charge transfer from the perovskite films to C₆₀ molecules.

To further reveal the thickness dependence and charge transfer process, we performed detailed XPS core level analysis. Figure 3 shows the XPS data of C 1s, O 1s, I 3d, and Pb 4f core levels with the different C₆₀ thickness. All the spectra have been normalized to the same height for visual clarity. In Figure 3(a), we observed the core levels for C 1s. There was a strong initial shift to lower binding energy when 2 Å C₆₀ deposited on the perovskite film. With the C₆₀ thickness increasing, the shift trend to the lower binding energy slowed down and saturated when the thickness reached to 128 Å. Besides that of C, all the other core levels are attenuated as the C₆₀ layer thickness increases, especially, the O 1s signal because it is weak as it comes from the oxygen contamination from the air.

In order to elucidate the XPS core level shifts more clearly, we show the energy level shift versus C₆₀ thickness in Figure 4. The inset is the amplified region for 2–16 Å C₆₀.
We observed the strong initial shift to lower binding energy when 2 Å C60 was deposited. The energy shift is about 0.3 eV. All other XPS spectra shifted to the lower binding energy as well. Then the core levels gradually shifted to higher binding energy for all the XPS spectra. The shifts for C 1s and O 1s are smaller than the shifts of N 1s, Pb 4f, and I 3d. It is not surprising, as the C 1s has increasing contribution from C60, and O is from the air contamination. When 8 Å C60 was deposited, the core levels began to shift to lower binding energies and finally saturated at 128 Å of C60. For all the spectra with different thickness of C60, we observe the same trend of shift. We could draw a conclusion that the

strong initial shift to the lower binding energy for all spectra indicated the electron transfer from the perovskite to the C60 molecule. Further deposition of C60 forms C60 solid, which results in a reduction of the electron transfer. The UPS results showed that with the C60 thickness increasing, the WF and HOMO levels shifted to the lower binding energy. Our XPS results have the same trend with the C60 thickness increase, especially when the thickness is over 8 Å, as the interface charge C60 electron transfer has completed and a rigid shift in the C60 is taking place.

The energy level diagram for 256 Å C60/perovskite interface is depicted in Figure 5. In Figure 5, the interface between perovskite and C60 has an interface dipole of 0.5 eV and HOMO onset BE of perovskite was measured to be 0.6 eV. The WF of the perovskite was measured to be 5.0 eV. Near the interface between perovskite and C60, the WF and VBM level were lifted up by 0.1 eV, which indicated the interface dipole as 0.5 eV. There is a clear band bending at the C60 region. The HOMO onset of C60 was measured to be 1.86 eV. With further C60 deposition a gradual relaxation was observed, resulting in a band bending region of ~200 Å. The energy level alignment indicated electron transfer from the perovskite to C60 molecule. These are high energy level electrons that may have acted as charge recombination/scattering centers, and removing them from the perovskite should contribute to the reduction in trap states observed in the device studies. With the C60 thickness increasing, the electron transfer reduced and finally saturated when the C60 thickness reached to 128 Å. We also compared the C60 band structures with the previous report.22 We notice that the pristine C60 has the HOMO and LUMO levels at 1.38 eV and −0.92 eV, respectively. In this case, we discovered that the C60 was n-type at the interface and became more neutral away from the interface as the HOMO level was pulled up and got closer to the Fermi level. Shao et al. also indicated that with thermal annealing process, the density of relatively shallow defect states reduced gradually, while there is rarely further reduction of deep trap density. It is possible that thermal annealing may drive C60 into the grain boundaries as individual molecules that act as strong electron absorbers as the 1/4 monolayer case, and further reduce the density of

defect states. We speculated the shallow trap states stay deeper in the perovskite films, such as grain boundaries inside the perovskite layer, which can only be passivated by the diffusion of C₆₀ into the perovskite layers.

In conclusion, we have measured the electronic structure evolution of C₆₀ on perovskite. We observed that the WF of the perovskite is 5.0 eV and the VBM is 0.6 eV. The band gap of the perovskite is 1.66 eV, which is in accordance with the previous reports. There is an interface dipole as 0.5 eV at the interface of perovskite and C₆₀. We also observed the HOMO level of C₆₀ shifts to lower binding energy, indicating a band bending in the C₆₀ region. The perovskite core levels show a strong initial shift to lower binding energy, indicating electron transfer from the perovskite film to fullerene molecules. The strongest electron transfer happened at 1/4 monolayer of fullerene, and further deposition reduced the transfer as forms fullerene forms C₆₀ solid film.
