1. Introduction

Smoking has consistently been reported as the number one preventable cause of premature death in the United States ([McGinnis and Foege, 1993] and [Mokdad et al., 2004]). Approximately 440,000 people die each year due to smoking-related diseases (CDC, 2005), and more than $75 billion in annual medical costs are directly attributed to smoking. In spite of these facts, in the U.S., 21% of adults are considered current smokers (CDC, 2005). Most smokers (ca. 70%) express a desire to quit (CDC, 2005) and approximately 40% report attempting to quit at least once in the past 12 months (CDC, 2005). Unfortunately, of those individuals that manage to quit, most relapse within the first few months of abstinence (NIDA, 2006). Although the processes responsible for tobacco use and nicotine dependence are complex, there is general consensus that the rewarding effects of nicotine are likely involved (see [Stolerman, 1991] and [Stolerman and Jarvis, 1995]). As such, a better understanding of the behavioral and neurobiological processes of nicotine reward is required.

Intravenous nicotine conditions a place preference in rats using an unbiased design

Abstract

The rewarding effects of nicotine contribute to the chronic use of tobacco products. The place conditioning task, a widely used pre-clinical model to study drug reward, has lead to mixed results in rats when nicotine was administered subcutaneously or intraperitoneally; intravenously administered nicotine has not been examined. Further, much of the research demonstrating a nicotine-conditioned place preference in rats has used a biased design making these results susceptible to non-reward interpretations. The present study assessed whether intravenous (IV) nicotine would condition a place preference in an unbiased design and evaluated important behavioral parameters: nicotine dose, number of conditioning trials, and infusion-to-placement interval. In adult male Sprague Dawley rats, IV nicotine (0.03 mg/kg) conditioned a place preference after 8 conditioning trials. This conditioned preference was observed whether nicotine was infused 10 min before or immediately after placement in the paired environment for 10 min; infusing nicotine immediately after removal from the paired environment did not condition a preference after 4 or 8 conditioning trials. Four conditioning trials were not sufficient to condition a preference regardless of the temporal relation between the paired environment and 0.03 mg/kg nicotine. A 0.01 mg/kg dose of nicotine did not condition a place preference after 4 or 8 trials when infused immediately upon placement in the paired environment. Intravenous nicotine (0.03 mg/kg) has rewarding effects in an unbiased design suggesting that the place conditioning protocol used in the present study might be an especially useful model for studying the processes underlying the conditioned rewarding effects of nicotine.

Keywords: Conditioned place preference, Nicotinic acetylcholine receptors, Pavlovian conditioning, Reward, Smoking,
ered rewarding if it produces an increase in the time spent in the environment paired with the drug compared to a control value [see Bevins and Cunningham (2006) for a more detailed discussion of methodological and measurement issues]. This increase in time in the drug-paired compartment is often referred to as a “conditioned place preference” and is thought to reflect a Pavlovian conditioned association between contextual stimuli and the rewarding effects of the drug (cf. [Bardo and Bevins, 2000], [Carr et al., 1989] and [Panksepp et al., 2004]).

Most drugs of abuse, such as amphetamine ([Erb and Parker, 1994] and [Lett, 1989]), cocaine ([Bevins and Bardo, 2000], [Bevins, 2005], [Nomikos and Sypriaki, 1988] and [O’Dell et al., 1996]), ethanol ([Cunningham et al., 1997], methamphetamine ([Cunningham and Noble, 1992] and [Gehrke et al., 2003]), and morphine ([Lett, 1989] and [Randall et al., 1998]), readily condition a place preference in rodents. Surprisingly, however, the results are less consistent with nicotine. Although the literature is mixed for rats and mice, the present research used rats and thus we will focus our discussion to the published research with rats [see Grabus et al. (2006) and Risinger and Oakes (1995) for research with mice]. Using rats some investigators have found that nicotine will condition an increase in time spent in the paired environment ([Ashby et al., 2002], [Calcagnotto and Schechter, 1994], [Dewey et al., 1999], [Forget et al., 2005], [Forget et al., 2006], [Fudala et al., 1985], [Fudala and Iwamoto, 1986], [Horan et al., 1997], [Horan et al., 2001], [Shoaib et al., 1994] and [Shram et al., 2006]). In contrast, other researchers have reported either avoidance (i.e., an aversion) of the nicotine-paired environment ([Fudala and Iwamoto, 1987], [Horan et al., 1997] and [Jorenbry et al., 1990]) or no place conditioning ([Acquas et al., 1989], [Carboni et al., 1989], [Clarke and Fibiger, 1987], [Rogers et al., 2004], [Shoaib et al., 1994] and [Shram et al., 2006]). Some potential factors that might explain the inconsistent results include age and strain of the rat, pre-exposure to nicotine, and use of a biased versus unbiased procedure (see LeFoll and Goldberg (2005) for a more detailed review).

Importantly, a majority (ca. 70%) of the published reports of nicotine place preference have used a biased design (see LeFoll and Goldberg, 2005). In a biased design, rats are initially given at least one free-choice test before conditioning as a screen for initial compartment (context) preference. During the conditioning phase, nicotine is then paired with the initially non-preferred compartment (i.e., often termed “conditioning against a preference”). An increase in time from the pre- to post-conditioning test is considered evidence for reward in a biased design. Of note, this biased design requires a control that never receives drug to determine how compartment preference would shift as a function of mere exposure to the environment. Further, unless a preference ratio (see later) or the time in the unpaired environment was reported, any increase in time from the pre- to post-conditioning test does not necessarily reflect a “preference” for the nicotine-paired compartment. That is, the animal might continue to spend more time on its initially preferred compartment, but still show an increase in time spent in the non-preferred (drug-paired) compartment (see Bevins and Cunningham, 2006). Although this shift in preference may reflect the conditioned rewarding effects of the drug (cf. Cunningham et al., 2003), alternate explanations for the shift in preference exist, thus complicating interpretation of any place conditioning result using a biased design (e.g., [Bardo and Bevins, 2000] and [Carr et al., 1989]). For example, the change in time spent in the initially non-preferred compartment might be measuring some anxiolytic or stress reduction property of the drug that decreases initial avoidance.

This discussion highlights the need to construct a balanced apparatus (i.e., no systematic preferences for either environment), as well as use an unbiased place conditioning design to facilitate interpretation of any results. In an unbiased place conditioning design, assignment of drug-paired environment is independent of any initial preference. Interestingly, there are very few published reports of nicotine conditioning a place preference in rats using an unbiased design. Indeed, LeFoll and Goldberg (2005) in a recent review of the literature only found 4 published papers, and these were all from the same laboratory (Ashby Jr.). Further, there have only been a few additional reports of a nicotine place preference using an unbiased design with rats since this review (e.g., [Forget et al., 2005] and [Forget et al., 2006]). The doses that produced a place preference in these studies (e.g., 0.06–0.21 mg/kg) are within the range of doses that others using the same route of administration (SC) have found no preference. With this discussion in mind, we used a balanced apparatus and an unbiased design in the present place conditioning experiments.

To our knowledge, there are no reports of place conditioning using intravenous (IV) administration of nicotine. This is somewhat surprising given the inconsistent findings using subcutaneous and intraperitoneal injections of nicotine (see LeFoll and Goldberg, 2005). Further, self-administration studies with rats consistently report that IV nicotine maintains instrumental responding over a range of doses (e.g., 0.06–0.21 mg/kg) (see LeFoll and Goldberg, 2005) are within the range of doses that other using the same route of administration (SC) have found no preference. With this discussion in mind, we used a balanced apparatus and an unbiased design in the present place conditioning experiments.

Intravenous nicotine conditions a place preference in rats
ence when it is administered before placement, but a place aver-
sion when it is administered immediately after exposure to the
context [(Cunningham et al., 1997) and (Cunningham et al.,
2002); for a comparable effect with cocaine see Ettenberg et al.
(1999)].

2. Materials and methods

2.1. Animals

Forty-five adult male Sprague–Dawley rats (329 ± 2.4 g)
from Harlan (Indianapolis, IN) were housed separately in poly-
carbonate tubs lined with wood shavings in a temperature- and
humidity-controlled colony. Rat chow and water were continu-
ously available in the home cage. All sessions were conducted
during the light portion of a 12:12 h light/dark cycle. Exper-
imental protocols were approved by the University of Nebraska–
Lincoln IACUC and followed the “Guide for the Care and Use
of Laboratory Animals” (National Research Council, 1996).

2.2. Surgery

Rats were anesthetized with 1 ml/kg ketamine hydrochlo-
ride (100 mg/ml, IP) followed by 0.6 ml/kg xylazine hydro-
chloride (20 mg/ml, IP) (Midwestern Veterinary Supply, Des
Moines, IA). One end of a silastic catheter was implanted into
the left external jugular vein. The other end of the catheter was
fed subcutaneously around the shoulder and exited via a back-
mount just below the scapula. The backmount allowed access
to the catheter through a metal cannula. Buprenorphine hydro-
chloride (0.1 mg/kg) was injected SC immediately following
surgery. For the evening and day following surgery, buprenor-
phine (0.5 mg/kg) was available in the drinking water to mange
post-surgical pain. For the evening of surgery and the follow-

2.4. Drug

(-)Nicotine tartrate (Sigma, St Louis, MO) was dissolved in
sterile saline and the pH was adjusted to 7.0 ± 0.2 with a dilute
NaOH solution. Nicotine infusions were 0.5 ml/kg and all nicot-
ine doses are reported as base.

2.5. Experiment 1A: place conditioning with 0.03 mg/kg nicotine

2.5.1. Habituation

Rats (n = 8) were attached to PE50 tubing connected to a sy-
ringe and then placed in the center compartment of the place
conditioning chamber. The prescribed volume of saline was in-
fused manually over 1 s and then the syringe was replaced with
another syringe of sterile saline and the tubing was cleared of
solution from the first syringe with 0.1 ml of sterile saline. The
tubing was then disconnected from the cannula and the rats
were allowed to freely explore the entire apparatus for 10 min.

2.5.2. Conditioning & testing (4 trials)

Conditioning occurred across 8 consecutive days with one
session per day. Half of the rats received 0.03 mg/kg nicotine
on days 1, 3, 5, and 7, and saline on opposite days; the order of
nicotine and saline was reversed for the remaining rats. During
a nicotine session, the rat was placed in the paired compartment
where it received an infusion of nicotine followed by 0.1 ml of
saline (see Habituation). Confinement to the paired compart-
ment was 10 min once the tubing was detached from the can-

Floors were used to create the distinct environments. One
floor had approximately 340 holes (1.3-cm diameter) drilled

2.5.3. Additional conditioning & testing (4 more trials)

Beginning the following day, conditioning was continued
exactly as described above for an additional 4 conditioning tri-
als (i.e., resulting in a total of 8 saline and 8 nicotine sessions).
The drug-free test was 24 h after the last confinement and was
detical to the previous drug-free test.
2.6. Experiment 1B: place conditioning with 0.01 mg/kg nicotine

After establishing that 0.03 mg/kg nicotine administered IV conditioned a place preference, we sought to test a lower dose of nicotine (0.01 mg/kg, IV). A separate and experimentally naive set of rats (n = 7) was conditioned and tested as described for Experiment 1A except 0.01 mg/kg nicotine was used instead of 0.03 mg/kg nicotine. All factors were counterbalanced as much as allowed by the sample size.

2.7. Experiment 2: role of interstimulus interval

2.7.1. Habituation

Habituation was similar to Experiments 1A and 1B. Rats were randomly assigned to the −10, 0, or +10 min group. The group name denotes the time between the intravenous infusion and placement in the chamber. Thus for habituation, the −10 min group (n = 7) was infused with saline and returned to the home cage for 10 min before placement in the center compartment of the place conditioning chamber. Rats in the 0 min group (n = 8) were infused immediately after placement in the chamber. This group served as a replication of Experiment 1A. The +10 min group (n = 7) was infused 10 min after placement (i.e., immediately after removal from the apparatus).

2.7.2. Conditioning & testing (4 trials)

Conditioning proceeded in a manner similar to Experiment 1A. Each infusion (saline and 0.03 mg/kg nicotine) was administered at the time point denoted by group assignment (i.e., −10, 0, or +10 min). The drug-free-choice test was identical to the previous experiment.

2.7.3. Additional conditioning & testing (4 more trials)

As in Experiment 1A, conditioning was continued for an additional 4 conditioning trials before conducting another drug-free test.

2.8. Dependent measures

For each choice test, we calculated a preference ratio using the following formula: time spent in the nicotine-paired compartment ÷ (time spent in the nicotine-paired compartment + time spent in the unpaired compartment). A preference ratio of 0.5 indicates no preference for either end compartment; a preference ratio greater than 0.5 indicates a preference for the paired compartment. Time in each compartment was scored during the test sessions. A rat was considered in a specific compartment when its front paws, head, and shoulders were in that compartment. Table 1 shows the mean time spent in the paired, unpaired (saline), and center compartments across the three experiments. Horizontal activity in each end compartment was also scored during each of the test sessions by counting the number of times the head and shoulders of the rat crossed a line that bisected each end compartment. Interobserver reliabilities for each measure was conducted from video by an observer naive to the experimental conditions. The Pearson-product moment correlations were high for the 66 observations made by both observers for time spent in each compartment, \( r = 0.93, p < 0.001 \), and for the 60 observations in common for line crosses, \( r = 0.97, p < 0.001 \).

2.9. Data analyses

One-way repeated measures ANOVAs were used to examine preference ratios across the 3 test sessions (habitation, 4 conditioning trials, and 8 conditioning trials) for Experiment 1A and 1B. A mixed two-way ANOVA with Session as the within-subject repeated factor and Interstimulus Interval as the between-subjects factor was used to analyze preference ratios for Experiment 2. Post-hoc analyses prompted by a significant \( F \)-value utilized one-sample \( t \)-tests to compare each preference ratio to a hypothetical value of 0.5 (i.e., the value indicating no preference). For analyses, activity counts were converted to a rate measure by dividing the number of line crosses in an end compartment by the time in seconds spent in that end compartment. A two-way ANOVA with Compartment and Session as the within-subject repeated measures factors was used to analyze activity data in Experiment 1A and 1B. Activity from Experiment 2 was analyzed using a mixed three-way ANOVA with Compartment and Session as repeated within-subject factors and Interstimulus Interval as the between-subjects factor. A significant interaction for activity data prompted post-hoc Fisher’s Least Significance Difference (LSD) tests. Comparisons were limited to those relevant for the significant interaction. Statistical significance was declared using a two-tailed rejection region of 0.05.

3. Results

3.1. Experiment 1A: place conditioning with 0.03 mg/kg nicotine

Preference scores on each of the drug-free tests are shown in Figure 1A. There was a main effect of Session, $F(2,14) = 4.07, p = 0.04$. The preference ratios for habituation and 4 conditioning trials were not different from 0.5, $t(7) < 1$. However, 0.03 mg/kg nicotine administered IV was able to condition a place preference after 8 conditioning trials as indicated by a preference ratio significantly above 0.5, $t(7) = 2.93, p = 0.022$. Activity scores are shown in Table 2. Although the main effect of Compartment and Session for activity were not significant, $F_s \leq 2.32, ps \geq 0.17$, there was a Compartment $\times$ Session interaction, $F(2,14) = 4.80, p = 0.026$. None of the follow-up Fisher’s LSD comparisons were significant (LSD = 0.08).

3.2. Experiment 1B: place conditioning with 0.01 mg/kg nicotine

Preference scores for rats conditioned with 0.01 mg/kg nicotine are shown in Figure 1B. There was no main effect of Session, $F_s < 1$, indicating that 0.01 mg/kg nicotine administered IV did not produce a place preference after 4 or 8 conditioning trials. None of the $F$-values for activity were significant, $F_s \leq 2.71, ps \geq 0.11$, (data shown in Table 2).

3.3. Experiment 2: role of interstimulus interval

Preference scores across the test sessions are shown in Figure 2. A mixed ANOVA on the preference scores revealed a main effect of Session, $F(2,38) = 5.98, p = 0.006$, and Group, $F(1,19) = 6.05, p = 0.009$; the Session $\times$ Group interaction was not significant, $F < 1$. Follow-up analysis indicated that preference ratios were significantly above 0.5 after 8 conditioning trials for the $−10$ min group, $t(6) = 2.84, p = 0.029$, and the 0 min group, $t(7) = 4.73, p = 0.003$, denoting that these temporal relations produced a place preference after 8 conditioning trials. No other preference ratio differed from the hypothetical value of 0.5, $ts \leq 1.67, ps \geq 0.14$. For activity, the Compartment $\times$ Session interaction was significant, $F(2,36) = 5.45, p = 0.01$; the main effects and remaining interactions for activity were not significant, $F_s \leq 3.06, ps \geq 0.08$, (see Table 2). None of the follow-up Fisher’s LSD comparisons were significant (LSD = 0.15).

4. Discussion

We found that intravenously administered nicotine (0.03 mg/kg) conditioned a place preference after 8 conditioning trials. This conditioned preference was observed whether nicotine was infused 10 min or immediately before placement in the paired

Figure 1. Panel A shows for each test session the mean preference ratios (+ 1 SEM) for rats ($n = 8$) in Experiment 1A that were conditioned with 0.03 mg/kg nicotine administered IV. Panel B shows the mean preference ratios (+ 1 SEM) for rats ($n = 7$) in Experiment 2A that were conditioned with 0.01 mg/kg nicotine administered IV. * indicates significant difference ($p < 0.05$) compared to hypothetical value of 0.5 (i.e., no preference).
context for 10 min. Infusing nicotine immediately after removal from the paired context did not produce place conditioning. At the 0.03 mg/kg dose of nicotine, 4 conditioning trials were not sufficient to condition a preference regardless of the interstimulus interval. Finally, the 0.01 mg/kg dose of nicotine when infused immediately upon placement in the environment did not condition a place preference after 4 or 8 conditioning trials.

For our initial attempt (i.e., Experiment 1A) we selected a dose of nicotine (0.03 mg/kg) that has been shown to maintain self-administration in rats across many laboratories (e.g., [Bevins, in press], [Corrigall and Coen, 1989], [DeNoble and Mele, 2006], [Donny et al., 1995], [Rauhut et al., 2003], [Shoaib et al., 1996] and [Cohen and Ettenberg, 2007]). Although there are some notable differences between what processes might be under investigation in place conditioning versus self-administration, there is also significant overlap in the list of drugs that will condition approach behavior and maintain instrumental responding (see Bardo and Bevins, 2000). Of note, this self-administered dose of nicotine required 8 conditioning trials to condition a place preference — 4 trials was not sufficient. This result is in concordance with those recently reported by Cohen and Ettenberg (2007). A conditioned increase in run speed down a straight alley was observed with 0.03 mg/kg nicotine IV and this increase appeared after more than 6 conditioning trials.

The lack of a nicotine-conditioned place preference after 4 trials was predicted by a casual observation made during the experiment. That is, rats were consistently defecating on the first few trials, with most stopping by the third conditioning trial. This observation was highly salient to us given that rats in our laboratory do not defecate to this extent in this apparatus when given cocaine or amphetamine. The defecation might be a result of the peripheral actions of nicotine which has been shown to stimulate intestinal smooth muscle and increase fecal pellets in rats (Aikawa and Ohmori, 2000). Alternatively, defecation has been used as a measure of fear and aversion (cf. [Bevins et al., 1997], [Fanselow, 1986] and [Hunt and Otis, 1953]) and suggested to us that the earlier exposures to nicotine might have some of these qualities (cf. Parker and Carvell, 1986). Such qualities could compete with any early rewarding effect of nicotine thus preventing acquisition of a conditioned place preference. Although we understand the possible difficulties with deriving conclusions from such observation, we felt that it was important to report this observation since it provided part of the impetus for conducting an additional four conditioning trials.

This observation also provided the impetus for assessing the lower dose of nicotine (0.01 mg/kg) in Experiment 1B. This dose of nicotine is on the lower end of the dose–effect curve that can maintain self-administration (e.g., Rauhut et al., 2003). Thus, we were looking for a dose that might not evoke early defecation, but have some rewarding effects. The 0.01 mg/kg dose of nicotine did not produce the early defecation nor did it condition a place preference. Notably, this dose of IV nicotine did not condition an increase in running speed in the Cohen and Ettenberg (2007) study even after 21 trials. Thus, under the present set of experimental parameters we found no evidence for reward at the 0.01 mg/kg dose. Additional manipulations such as more conditioning trials and briefer chamber exposure with this lower dose of nicotine will be of interest in future studies.

There is a substantial Pavlovian conditioning literature indicating the importance of the temporal arrangement between the to-be-conditioned stimulus and the reinforcer (unconditioned stimulus) for acquisition of conditioned responding. The conditioning tasks demonstrating the importance of the interstim-
ulus interval have been as varied as eye-blink conditioning in humans (McAllister, 1953), aversive conditioning in goldfish (Bitterman, 1964), key-peak autoshaping in pigeons (Gibson et al., 1977), context fear conditioning in rats (Bevins and Ayres, 1995), nicotine-conditioned hyperactivity in rats (Bevins et al., 2005), and ethanol place conditioning in mice (Cunningham et al., 1997). The present research extended this list to include place conditioning with IV administered nicotine. In brief, 0.03 mg/kg nicotine administered immediately or 10 min before confined exposure to the paired environment for 10 min conditioned a place preference after 8 conditioning trials. IV administration of nicotine immediately after removal from the paired compartment (i.e., −10 min group) had no apparent effect on choice behavior after 4 or 8 conditioning trials (i.e., no approach or avoidance tendencies). This data pattern suggests that the rewarding effects of IV nicotine extend long enough that there is sufficient temporal contiguity between the to-be-paired compartment and nicotine to condition an appetitive association.

Interestingly, under some experimental protocols the interstimulus interval can reveal different motivational properties of the same drug. For example, alcohol (2 g/kg, 20% v/v) given IP to mice conditioned a place preference when administered before placement in the paired context, but the same dose conditioned an aversion when administered immediately after exposure to the context [Cunningham et al. (1997); see also Ettenberg et al. (1999) for research with cocaine]. Although we did not find evidence for this dual property/opponent process for nicotine in the present study, it will be of interest to examine different doses on IV nicotine against different interstimulus intervals, context confinement durations, etceteras.

As noted in the Introduction, much of the nicotine place conditioning research demonstrating a place “preference” has used a biased design (i.e., nicotine paired with an initially identified non-preferred compartment). Unfortunately, using a biased design introduces alternative non-reward explanations for preference shifts such as stress reduction or anxiolytic effects of the drug ([Bardo and Bevins, 2000], [Carr et al., 1989] and [Bevins and Cunningham, 2006]). To avoid such difficulties, the present research used an apparatus with balanced construction and an experimental design that was unbiased. As evidence of the balanced construction of our place conditioning apparatus, rats (n = 37) averaged across the three experiments in the present study spent 260.9 ± 8.8 s on the rod floor and 251.8 ± 7.4 s on the hole floor during habituation. By assigning rats to paired versus unpaired environment irrespective of their performance on the habituation day, the shifts in preference for the paired compartment at the 0.03 mg/kg dose of nicotine are less susceptible to non-reward interpretations.

Related to the previous discussion, some researchers have suggested that differential patterns of locomotor activity between the drug-paired and unpaired environments on the test day could complicate interpretation of a place conditioning effect (e.g., [Parker, 1992] and [Swerdlow and Koob, 1984]). This potential interaction could be important for the present research given that an environment reliably paired with nicotine administered SC comes to evoke a conditioned increase in activity on a drug-free test ([Bevins et al., 2001], [Bevins et al., 2005] and [Walter and Kuschinsky, 1989]). To assess a possible role of motor activity, we scored line crosses in each end compartment across all free-choice test sessions. Although there was a Compartment × Session interaction in each experiment showing place conditioning, the post-hoc analyses did not reveal any significant differences in activity. Further, any trend seen in the mean activity scores was the opposite of that expected if conditioned hyperactivity was evident. That is, rats were slightly more active in the unpaired compartment relative to the paired compartment. Thus, an account of our nicotine place conditioning results with 0.03 mg/kg nicotine based on conditioned alterations in motor activity seems unlikely.

Given the discussion in the previous paragraphs, we suggest that 0.03 mg/kg IV nicotine has rewarding effects that are readily measured in a place conditioning task. Conditioned associations and reward processes involving nicotine likely contribute to tobacco use and the tenacity of nicotine dependence (e.g., [Bevins and Palmatier, 2004], [Rose and Levin, 1991] and [West and Schneider, 1987]). Accordingly, a better understanding of these processes will contribute to designing better intervention strategies for smoking cessation. With this goal in mind, we suggest that the IV nicotine place conditioning protocol used in the present study might be an especially useful model for studying the processes underlying the conditioned rewarding effects of nicotine. Of course, adoption of such a recommendation will require replication by other laboratories. This replication and hence adoption might be slowed by the added technical, temporal, and fiscal burden of catheter surgeries and maintenance.

Acknowledgments

We thank Jonathan Fullner and Jill Rosno for scoring the behaviors used to assess interobserver reliability and Jessica Linkugel, Jennifer Murray, Carmela Reichel, and Amanda Struthers for their thorough read of an earlier version of this manuscript. The research and R. A. Bevins were supported by United States Public Health Service grant DA018114 and DA017086. Jamie Wilkinson was supported by Nebraska Tobacco Settlement Biomedical Research Enhancement Funds while preparing this manuscript for publication.
