Abstract

The wheat curl mite (WCM), *Aceria tosichella*, is an important pest of wheat and other cereal crops that transmits wheat streak mosaic virus and several other plant viruses. Wheat curl mite has long been considered a single polyphagous species, but recent studies in Poland revealed a complex of genetically distinct lineages with divergent host-acceptance traits, ranging from highly polyphagous to host-specific. This diversity of WCM genotypes and host-acceptance phenotypes in Europe, the presumed native range of WCM, raises questions about the lineage identities of invasive WCM populations on other continents and their relationships to European lineages. The goals of this study were to examine the global presence of WCM and determine the relatedness of lineages established in different continents, on the basis of phylogenetic analyses of mitochondrial and nuclear DNA sequence data. Host-range bioassays of a highly polyphagous WCM lineage were performed to supplement existing data on this lineage's ability to colonise graminaceous and non-graminaceous hosts. Invasive WCM populations in North and South America and Australia assorted with the only three known polyphagous and pestiferous WCM lineages ('MT-1', 'MT-7' and 'MT-8') from a total of eight currently described lineages. These results show that the most polyphagous lineages were more successful colonisers and reflect a need for extensive surveys for WCM on both crops and wild grass species in invaded continents. The most invasive lineage ('MT-1') was shown to successfully colonise all 10 plant species tested in three families and has spread to North and South America and Australia from its presumed origins in Eurasia.

Introduction

Increased intercontinental tourism and trade favour the worldwide dissemination of taxa that are otherwise constrained by geographical barriers, resulting in environmental, ecological and economic impacts on biological communities and ecosystems (e.g. Pimentel *et al.*, 2000). Invasive species may adversely alter communities of native species, thereby modifying ecosystem functions and creating major problems for agriculture through the

transmission of diseases and pathogens, as well as direct damage to crops (e.g. Honek & Martinkova, 2011; Benheim *et al.*, 2012; Mazzi & Dorn, 2012; Juárez-Escario *et al.*, 2013; Wang *et al.*, 2013).

Eriophyoid mites are phytophagous arthropods that have high potential as invasive organisms because their minute size makes them difficult to detect. As such, they can be easily distributed through trade or other movement of their host plants. Eriophyoidea include many important pests of agriculture and forestry worldwide, responsible

for yield losses via direct damage or disease transmission (Oldfield & Proeseler, 1996; Duso *et al.*, 2010). Eriophyoid species have been reported as invasive and represent quarantine concerns in numerous countries (Navia *et al.*, 2010). The implementation of appropriate control and risk mitigation strategies for eriophyoid mites can be hampered by the difficulty of taxonomic identification due to their microscopic size and their morphological simplicity and ambiguity under current descriptions (Lindquist & Amrine, 1996). The existence of cryptic, often host-associated, genetic lineages can also confound such efforts (Magalhães *et al.*, 2007; Skoracka *et al.*, 2012). Recent molecular genetic studies have detected cryptic species complexes in eriophyoid mites (Carew *et al.*, 2009; Skoracka & Dabert, 2010; Miller *et al.*, 2013; Skoracka *et al.*, 2013). Elucidation of such ill-defined taxonomic relationships for agriculturally important Eriophyoidea is critical to the development of tools such as efficient diagnostic keys that integrate morphological, behavioural and molecular characters to facilitate targeted control of pestiferous lineages.

The majority of eriophyoid species are known to be highly host-specific (Skoracka *et al.*, 2010), whereas the wheat curl mite (WCM), *Aceria tosichella* (Keifer) (Acari: Prostigmata: Eriophyoidea), has been commonly characterised as a single, highly polyphagous species with >80 species of *Poaceae* recorded as hosts (Navia *et al.*, 2013). The WCM is an important pest of wheat and other cereal crops (e.g. barley, corn, oat, pearl millet, rye, sorghum), with direct yield losses to wheat reaching 30% (Styer & Nault, 1996; Harvey *et al.*, 2002; Navia *et al.*, 2010). The mite is also known to transmit several plant viruses, including wheat streak mosaic virus (WSMV), a major pathogen of wheat in North and South America, Europe, the Middle East, Oceania and Asia, that can cause complete crop loss in infested fields (Navia *et al.*, 2013). Other plant diseases transmitted by WCM include wheat spot mosaic virus (Jeppson *et al.*, 1975), brome streak mosaic virus (Stephan *et al.*, 2008), High Plains virus (Seifers *et al.*, 1997) and triticum mosaic virus (Seifers *et al.*, 2009). The latter three can occur in mixed infections with WSMV (Byamukama *et al.*, 2013). Wheat curl mite and its associated viruses have been recorded as major yield reduction factors of wheat crops in North America for about 60 years and in recent decades the mite has emerged as a serious threat to cereal production in Australia and South America (Navia *et al.*, 2013).

Recent phylogenetic analyses of DNA sequence diversity have revealed the existence of different genotypes or perhaps cryptic species within *A. tosichella* (*sensu lato*). Carew *et al.* (2009) identified two distinct WCM lineages present in several invasive Australian populations collected from wheat and other grass hosts.

These two lineages were shown to have overlapping geographical distributions, while only one lineage is implicated in WSMV transmission (Schiffer *et al.*, 2009). Hein *et al.* (2012) found two genetically distinct WCM populations in North America that corresponded to the Australian mite populations. Moreover, a comprehensive phylogenetic analysis of WCM from different host plants and on four continents revealed several additional unique WCM lineages with species level differences in sequence diversity (Skoracka *et al.*, 2012; Miller *et al.*, 2013). A study of WCM genetic and host-range variability in western Poland identified seven genetic lineages (designated 'MT-1' through 'MT-7') with variable host ranges, including divergent host-acceptance and specificity traits. Genetic variation for host-acceptance may act as a pre-zygotic reproductive barrier between these lineages (e.g. Schluter, 2001; Nosil, 2007). Lineages ranged from highly polyphagous and pestiferous to more host-specific, including several WCM lineages, collected from wild grass species, that were not able to colonise wheat (Skoracka *et al.*, 2013). Of the seven lineages collected in Poland, only one (MT-1) showed the highly polyphagous habit that is commonly associated with WCM, attacking nine of ten test species in host-acceptance experiments, including wild and cultivated grasses as well as cultivated *Allioidae* and *Liliaceae* but excluding maize (Skoracka *et al.*, 2013). Host-range bioassays on the polyphagous MT-1 lineage were performed in this study to supplement existing data on its ability to colonise maize, garlic, onion and tulip. The great diversity of genotypes and host-acceptance phenotypes found in Poland raises questions about the lineage identities of invasive WCM populations on other continents compared to European lineages. To date, no comprehensive study has attempted to unequivocally delineate the native range of WCM although the variety of lineages found on both domesticated and wild grass species in Europe (Skoracka *et al.*, 2012; Miller *et al.*, 2013) suggests that it overlaps with the southwest Asian ('fertile crescent') origins of cereal species.

The goals of this study were to examine the global presence of WCM and determine whether the lineages that have become established in Australia and North and South America are related to lineages that have been described in the putative native range of WCM in Europe. We hypothesise that spread of WCM is associated with the global trade in agricultural plants and that lineages found in recent intercontinental invasions of WCM would have arisen from the most pestiferous and polyphagous European lineages. In short, lineages most able to reproduce on crop species would be most likely to spread to new continents. The existence of numerous genetically distinct WCM lineages with divergent

host-ranges, in addition to the worldwide spread of WCM, provides a system through which invasion potential could be examined *post hoc* within a single species complex on the basis of host-range and human association.

Materials and methods

Experiments testing the host colonisation ability of MT-1 lineage

The stock colony

Specimens of WCM lineage MT-1 [detected in previous study: Skoracka *et al.* (2013), (GenBank: JF920077)] originating from the stock colony maintained on bread wheat *Triticum aestivum* L. for several months in the laboratory of Department of Animal Taxonomy and Ecology, Faculty of Biology, Adam Mickiewicz University were used in these experiments. Details for preparing the stock colony are described in Skoracka *et al.* (2013).

Experimental plants

Three cereal species: bread wheat var. Tonacja (as control), triticale (\times *Triticosecale* Wittm. ex A. Camus) var. Hortenso, maize (*Zea mays* L.) var. Mas22.R; two economically important *Amaryllidaceae* species: bulb onion (*Allium cepa* L.) var. Red Baron and garlic (*Allium sativum* L.) var. Harnaś; and one ornamental *Liliaceae* species: Didier's tulip (*Tulipa gesneriana* L.), were used as experimental plants. Cereals were grown from commercially available seeds in pots and kept in cages. Bulbs of garlic, onion and tulip were cleaned and checked for the presence of any arthropods or disease symptoms before being used.

Mite colonisation test

Previous experiments (Skoracka *et al.*, 2013) showed that females of the MT-1 lineage successfully colonised wheat, barley and triticale when transferred directly from wheat in small numbers; however, they did not attain high population growth on maize. Given that a population of WCM was collected from the field on maize subsequent to that study (see Table 1) and given that MT-1 was the most polyphagous known WCM lineage, a new colonisation test was performed to determine if MT-1 could move from heavily infested wheat plants to clean maize plants. Cut shoots of wheat plants infested with MT-1 mites from stock colonies were placed in contact with clean shoots of laboratory-grown wheat, triticale or maize plants and were removed after 24 h. The densities of MT-1 populations in the stock colony were estimated and the number of mites per shoot ranged from 100 to

210 (mean = 170). Experimental plants were inspected after 14 and 29 days. Experimental plants were not destroyed during the first inspection, that is 14 days post-infestation, therefore exact counts of mites were not made at this time although estimation of population increase on the test plants was made in order to check whether mites had colonised plants and whether they were reproducing. During the second inspection, 29 days post-infestation, plants were destroyed and all mites were counted. Some mites were preserved in ATL buffer (Qiagen GmbH, Hilden, Germany; a tissue lysis buffer for use in purification of nucleic acids) for subsequent genotyping. Additional test plants with mites were kept until 45 days post-infestation, however, quantitative data were not possible to obtain after that time due to very high population densities. Thus, for these last observations the only information gathered was whether the population was still thriving after 45 days and mites were collected in ATL buffer for genotyping. For each plant species tested, four trials (repetitions) were carried out. Eight plants per treatment per trial were used. Experimental plant species with mites were maintained separately in rearing cages under stable conditions (20–21°C, 50–60% humidity).

Population growth on Amaryllidaceae and Liliaceae

Previous experiments (Skoracka *et al.*, 2013) demonstrated that females of the MT-1 lineage successfully colonised bulbs within 14 days of infestation when transferred directly to garlic, onion and tulip. However, it was not known if the grass associated MT-1 lineage would continue its development and reproduction after a longer time on plants belonging to families other than *Poaceae*. To answer this question, an experiment with a longer duration was conducted. MT-1 females from stock colonies were transferred to clean potted wheat plants (control) and clean bulbs of *Amaryllidaceae* (garlic and onion) and *Liliaceae* (tulip). Eriophyoid mites reproduce by arrhenotoky whereby young females pick up spermatophores dropped by males (Michalska *et al.*, 2010). Thus, MT-1 females transferred from an active colony to new plants in these studies were likely to have been fertilised; eggs of unfertilised females can still develop parthenogenetically and produce all male offspring. For each test-plant species, five trials (repetitions) were carried out. A trial was defined as a single plant or bulb with 15 females transferred to them. Thus, for each test-plant species 75 females were transferred (300 females in total). Ten minutes after mite transfer, plants and bulbs were checked to count the number of females that had successfully settled on them. This number was defined as the number of females engaged in the experiment for a given trial (hereafter 'experimental females'). Females that appeared

COI, cytochrome c oxidase subunit I; GPS, Global Positioning Satellite; ITS, internal transcribed spacer; WCM, wheat curl mite.

^aReferences for GenBank sequences: 1, Hein et al. (2012); 2, Skoracka et al. (2012); 3, Carew et al. (2009); 4, Skoracka et al. (2013); ts, this study.

dead or injured during the post-transfer inspection were removed from the plants and bulbs (*ca.* 3%). Experimental plants and bulbs with transferred females were kept in cages (as described above) under laboratory conditions (20–21°C, 50–60% humidity) for 28 days post-infestation. Plants and bulbs were then inspected and the number of mites was counted using a stereomicroscope. Mites were collected from test plants and preserved for molecular analysis (see below). After this inspection, bulbs were kept under laboratory conditions for 85 days post-infestation (tulip) or 150 days post-infestation (garlic and onion), after which they were again checked for the presence of mites. It was not possible to obtain quantitative data at that time due to very high population densities. Mites were again collected for genotyping.

Experimental data analysis

To quantify colonisation ability of the MT-1 lineage on different hosts a simple population growth model was applied:

$$\ln(n_t/n_0)/t = r_i$$

where r_i is the effect for host plant i (mean daily population growth rate), n_t is population size at time t and n_0 is the initial population size. This model implies that the number of individuals in the population changes as a fraction of n_0 at a constant rate, which varies only across different host plants. To estimate r for each trial (in both transfer and colonisation experiments) we fitted a linear model to log-transformed counts made at two different time points. The slope parameter r from these fitted models is a measure of mean daily population growth rate. In the case of the transfer experiments, n_0 was the exact count of females which successfully settled (i.e. females transferred minus dead or injured), and n_t was the number of all specimens found after 28 days. A complete life cycle of WCM takes 8–10 days under favourable conditions, and at most 13 days at 20°C (Navia *et al.*, 2013). Thus, after 28 days a third generation of mites in the experimental population would be expected in the case of successful colonisation. In the colonisation test, population counts were made after 14 and 29 days. As the leaves used for these experiments were clean, the initial number of individual mites on test plants at the beginning of each experiment was zero. To account for this, the linear model used to estimate r was fit without an intercept in colonisation experiments.

To test if r differed significantly between test plants, a simple ANOVA was performed. Pairs of mean population growth rates were compared using least significant difference (LSD) values at the 0.05 level of significance. Ninety-five percent confidence intervals around means

of r (CI hereafter) were calculated using bias corrected and accelerated bootstrap (Efron & Tibshirani, 1993). For computations, R 3.0.2 was used (R Development Core Team, 2013).

Molecular analyses

Specimens collection

Field-sampled WCM populations were collected from the following plant species and countries: bread wheat, triticale, maize and smooth brome were sampled in Poland, bread wheat and wall barley in Turkey, and bread wheat in USA [Nebraska (NE) and Texas (TX)] (Table 1). Specimens from Poland and Turkey were collected in 2009–2012 into Eppendorf tubes containing 180 µL of ATL buffer (Qiagen GmbH) for DNA extraction while US specimens were collected in 1998 as described by Harvey *et al.* (1999). Wheat curl mite populations from USA were maintained as established colonies and stored as previously described (Hein *et al.*, 2012). The morphological identification of WCM was confirmed by examining slide-mounted specimens from each extracted sample with a phase-contrast microscope.

DNA extraction, amplification and sequencing. For specimens from Poland and Turkey stored in ATL buffer, a non-destructive method of DNA isolation, as described by Dabert *et al.* (2008), was performed. The number of specimens used for each DNA extraction varied from one to several. The cytochrome *c* oxidase subunit I (COI) gene fragment was amplified by PCR with the degenerate primers bcdF01 and bcdR04 (Skoracka & Dabert, 2010). The PCR was carried out in 10 µL reaction volumes containing 5 µL Type-it Multiplex PCR Master Mix (Qiagen GmbH), 0.5 µL of each primer and 4 µL of DNA template. A thermocycle profile of one cycle of 5 min at 95°C followed by 35 steps of 30 s at 95°C, 30 s at 50°C, and 1 min at 72°C, with a final step of 15 min at 72°C was applied. The ribosomal DNA (rDNA) fragment containing complete ITS1, 5.8S and partial ITS2 regions was amplified with the primers f1230 (Skoracka & Dabert, 2010) and 28Srev430 (CAACTTCCCTCACGGTACTTGT-3'). The PCR followed a similar procedure as for COI, except that primers were diluted twofold and the elongation time of PCR was 2 min instead of 1 min. The PCR products were diluted with 10 µL of water and 3 µL of the product was analysed by electrophoresis in a 1% agarose gel. Samples containing visible, single bands were directly sequenced in both directions using 0.5–1 µL of the PCR product and 50 pmol of the corresponding sequencing primer, that is bcdF01 and bcdR04 for COI, and ITS1-18S (Navajas *et al.*, 1999) and 28Srev430 for ITS1, 5.8S and ITS2. Sequencing was performed with

BigDye Terminator v3.1 on an ABI Prism 3130XL or 3730 Analyzer (Applied Biosystems, Foster City, CA, USA). Trace files were checked and edited using MEGA5 (Tamura *et al.*, 2011).

For the USA-NE and USA-TX WCM populations, 1–5 mites were collected from infested plants or preserved samples and placed in 0.5 mL PCR reaction tubes in 20 μ L 1 \times PCR buffer (Roche, Indianapolis, IN, USA) and stored at -20°C until PCR assays were performed. Prior to PCR, mite-containing tubes were heated to 99°C for 5 min and then placed on ice. PCR primers 16SF (5'-AATCAAAAGTCTATTAATTGTAGACCTG-3') and COIR (5'-ATAGAAATAGTAGCTAATCAACTAA-3') at 0.5 μM final concentration, deoxynucleotide triphosphates (dNTPs) (final concentration of each 0.2 mM), 4 μL 10 \times PCR buffer, and 1.25 units Expand High Fidelity System (Roche) were added to each tube, in addition to sufficient sterile water to make a final volume of 50 μL . PCR amplification was carried out with 35 cycles of 94°C for 1 min, 52°C for one min, and 72°C for 4 min. Following PCR amplification, the ~ 2.5 kb DNA products were purified using High-Pure spin columns (Roche) and stored at -20°C before ligation into T-tailed pGEM-T Easy (Promega, Madison, WI, USA) and transformed into *E. coli* JM109. Nucleotide sequences of both strands were obtained by automated sequencing (Davis Sequencing, Inc., Davis, CA, USA) by primer walking using a minimum of three independent clones per sequence. Automated sequence data were compiled using Sequencher 4.1 (Gene Codes, Ann Arbor, MI, USA). All sequences have been deposited in GenBank under the accession numbers listed in Table 1.

Sequences from GenBank. To assess the global distribution of WCM lineages, additional sequences were obtained from WCM populations collected on bread wheat in Australia and South America, wall barley in Australia and rescuegrass in Australia; all deposited in GenBank by Skoracka *et al.* (2012). Sequences of the MT-7 lineage from Poland that was specific to wild and cultivated barley (*Hordeum* spp.) were also included in the phylogenetic analysis, in addition to the MT-1 lineage collected from quackgrass, smooth brome and tall oat-grass (Skoracka *et al.*, 2013). Additional analyses were performed on sequences of a nuclear internal transcribed spacer region (ITS1) obtained from WCM populations in Europe, Australia and North and South America deposited in GenBank by Skoracka *et al.* (2012), Carew *et al.* (2009) and Hein *et al.* (2012). Accession numbers for all analysed sequences are listed in Table 1. *Aceria eximia* Sukhareva from the wood small-reed, *Calamagrostis epigejos* (L.) Roth was chosen as an outgroup for molecular analyses (GenBank: EF409415 for COI and JF920113 for ITS1).

Sequence analyses. Cytochrome *c* oxidase subunit I and nuclear rDNA sequences were aligned separately by CLUSTALW using MEGA 5 (Tamura *et al.*, 2011) with default gap weighting parameters, followed by manual adjustment. Alignment of the COI sequences covering 603 bp of the 5' terminus of COI gene was checked by translating the aligned DNA into amino acids. We used two datasets of rDNA sequences. One alignment, containing ITS1 sequences from different continents (sourced from GenBank), was cut to a uniform length of 348 bp since most of the available ITS1 sequences were of this length. The second alignment contained additional sequences obtained under this study from the MT-1, MT-7 and MT-8 lineages. The rDNA forward and reverse sequences were aligned and assembled to form a 755 bp sequence covering ITS1, 5.8S and part of the ITS2 region. These longer sequences were used to compare the MT-1, MT-7 and MT-8 lineages, as they were more informative than the shorter (348 bp) sequences.

The best-fit models of nucleotide substitution were selected with jModeltest ver. 2.1.4. (Guindon & Gascuel, 2003; Darriba *et al.*, 2012) based on likelihood scores for 88 different models, Akaike Information Criterion (AIC) and Bayesian Information Criterion (BIC). The TPM3uf+I model (Kimura, 1981; Posada, 2008) was chosen as the best model for the maximum likelihood (ML) analysis for COI sequences according to AIC. Estimated base frequencies were: A=0.22, C=0.17, G=0.15, and T=0.46 and the proportion of invariable sites was (p-inv)=0.6700. The HKY+I substitution model (Hasegawa *et al.*, 1985) was chosen for the Bayesian inference (BI) of phylogeny for COI sequences according to BIC, with the same estimated base frequencies as above. The transition/transversion ratio was (ti/tv)=6.8831 and the proportion of invariable sites was (p-inv)=0.6760. For the nuclear rDNA datasets, the TPM2 substitution model (Kimura, 1981; Posada, 2008) was chosen for ML with equal base frequencies and the K80 model (Kimura, 1980) was chosen for BI.

Pairwise distances between nucleotide sequences were calculated using PAUP* 4.0b10 (Swofford, 2003) with graphical frontend PaupUp v.1.0.3.1 for Windows (Calendini & Martin, 2005). The Kimura 3-parameter model (Kimura, 1981) [K81, modified to TPM3 by Posada (2008)] with proportion of invariable sites was applied for the COI dataset and the general time-reversible (GTR) model set with jModeltest generated PAUP* block was applied for the ITS1, 5.8S and ITS2 dataset, according to prior jModeltest estimates. The mean within- and among-lineage distances with standard error estimates obtained using a bootstrap procedure (1000 replicates) were calculated in R 3.0.2 (R Development Core Team, 2013).

Since in many studies the genetic distances are not calculated with models chosen for specific data [recently criticised by Srivathsan & Meier (2012)], the uncorrected p -distances with standard error estimates (obtained with a bootstrap procedure; 1000 replicates) were also calculated using MEGA5 (Tamura *et al.*, 2011). This simple distance measure was implemented to optimise estimates of both intra- and inter-lineage genetic variation, as in other studies of invertebrate diversity (e.g. Lim *et al.*, 2012; Hsu *et al.*, 2013; Schwentner *et al.*, 2013).

Additional analysis of COI sequences was carried out in order to construct the BI tree presenting the lineages discussed in this study in relation to all WCM lineages detected thus far (Skoracka *et al.*, 2013). For this analysis the HKY + G model was chosen by jModeltest. Estimated base frequencies were: A = 0.24, C = 0.14, G = 0.13, and T = 0.49, the gamma shape parameter was (G) = 0.1730, and the transition/transversion ratio was (ti/tv) = 7.1572.

Maximum likelihood analyses were performed with PhyML 3.0 (Guindon *et al.*, 2010). Analyses were set to optimise branch lengths and the tree topology search method used a nearest neighbour interchange algorithm. For each ML analysis, the approximate likelihood-ratio test (aLRT) (Anisimova & Gascuel, 2006) was performed. Bayesian inference approach estimation of phylogenetic relationships was performed with MrBayes v.3.2 (Ronquist *et al.*, 2012). For each dataset, two independent runs were performed and each consisted of four chains with number of generations developed until the average standard deviation of split frequencies was less than 0.01. A 50% majority consensus tree with posterior probability values was composed out of obtained trees, with exclusion of 25% of trees produced at the beginning of the analyses.

Results

Host colonisation ability of the MT-1 lineage

The colonisation tests showed that mites belonging to the MT-1 lineage (confirmed by COI sequence, sequences identical to JF920077) can successfully colonise wheat ($r=0.28$; CI: 0.27–0.28), triticale ($r=0.29$; CI: 0.28–0.30), and maize ($r=0.19$; CI: 0.18–0.19) by moving from adjacent, infested wheat plants, although the population growth rate was significantly lower on maize compared to the other two cereal species (Fig. 1). The results of the 28-day observations of MT-1 mites showed that colonisation of garlic ($r=0.12$; CI: 0.10–0.13), onion ($r=0.10$; CI: 0.10–0.11) and tulip ($r=0.11$; CI: 0.10–0.11) was successful, although the population growth rate was significantly lower on *Amaryllidaceae* and *Liliaceae* compared to wheat (Fig. 2). Genotyping confirmed that the MT-1 lineage colonisation of

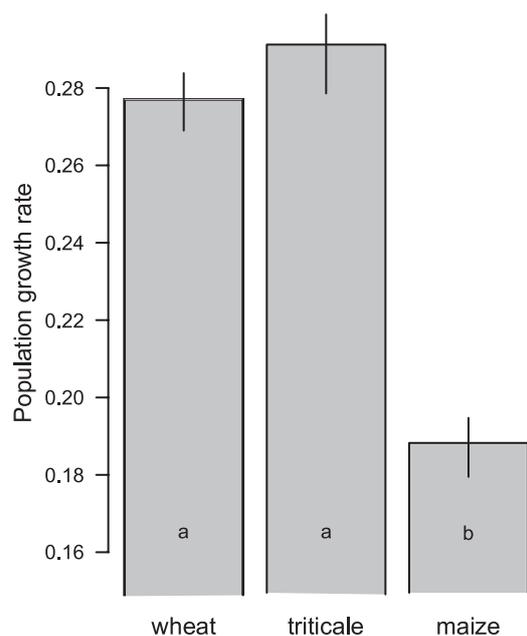

Figure 1 Population growth rates (r) of the wheat curl mite MT-1 lineage engaged in host colonisation tests. Bootstrapped 95% confidence intervals around means of r are shown. Treatments with the same letter were not significantly different (least significant difference test).

tulip was still active after 3 months and garlic and onion after 5 months, reaching very high population densities (data not shown).

Phylogenetic analyses

The COI dataset consisted of 21 aligned sequences of 603 bps representing 11 unique haplotypes (unique sequences) of WCM (i.e. *Aceria tosichella sensu lato*) and one outgroup species. No insertions or deletions were found. Within the alignment, 156 positions were variable. The Kimura 3-parameter plus invariable sites COI genetic distance among all sequences (including outgroup) ranged from 0% to 32.3%, and averaged 17.2% (SE = 0.8%), whereas distances among WCM sequences ranged from 0% to 28.1% and averaged 15.8% (SE = 0.8%). The uncorrected p -distance among all sequences (including outgroup) ranged from 0% to 19.4%, and averaged 11.2% (SE = 1.0%), whereas among WCM sequences it ranged from 0% to 17.1% and averaged 10.4% (SE = 1.0%). Structures of the phylogenetic trees inferred by BI and ML consistently showed the same topology (Fig. 3). Wheat curl mite sequences clustered into three distinct and well supported lineages (≥ 0.98 for BI and 81 for ML). Two of the lineages comprised COI genotypes that were previously designated MT-1 and MT-7. The third

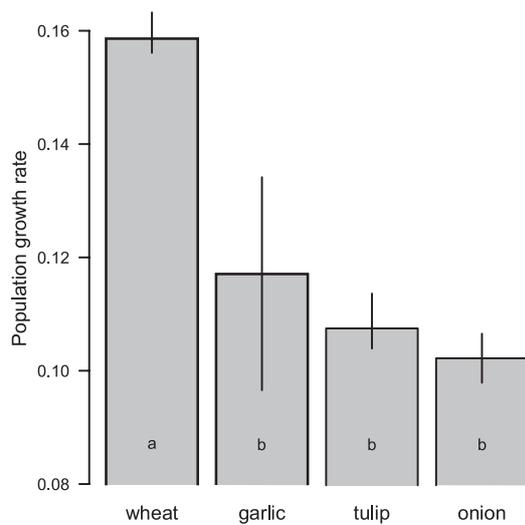

Figure 2 Population growth rates (r) of the wheat curl mite MT-1 lineage when transferred to *Amaryllidaceae* and *Liliaceae* plants. Bootstrapped 95% confidence intervals around means of r are shown. Treatments with the same letter were not significantly different (least significant difference test).

lineage is designated here as MT-8 (Fig. 3). The intra-lineage Kimura 3-parameter and p -distance divergences were both $<1\%$ (0.3–0.7%), whereas the inter-lineage Kimura 3-parameter divergence was $>17\%$ and ranged from 17.5% to 26.2%, and the inter-lineage p -distance divergence was $>11\%$, ranging from 11.3% to 14.4%. Pairwise comparisons of the COI distances within and between WCM lineages and between lineages and outgroup species are presented in Table 2. The MT-1 populations analysed here were collected from five different plant species, viz. wheat and four wild grasses, and MT-1 was found on wheat on all five continents surveyed, viz. North and South America, Europe, Asia, Australia (Fig. 3). The MT-7 lineage included populations infesting wheat and wall barley and was found in Europe, Asia and Australia (Fig. 3). The MT-8 lineage was collected from three cereal species and one forage grass species and was found in North America, Europe, Asia, Australia (Fig. 3). The three invasive lineages were shown to be genetically distinct from the other European lineages described thus far (Fig. 5) in addition to having been recorded from multiple hosts, including domesticated cereals, unlike the other known European lineages (Skoracka *et al.*, 2013).

The complete ITS1 dataset consisted of 19 aligned sequences of 348 bps representing 18 sequences of WCM and one outgroup sequence. Within the alignment, 31 positions were variable. The uncorrected p -distance (including the outgroup taxon) ranged from 0% to 8.6% and averaged 1.4% (SE = 0.3%). The mean uncorrected

Table 2 Percentage average Kimura 3-parameter with invariable site distances (upper) and uncorrected p -distances (lower) (with standard error estimates in parentheses) for mtDNA COI gene sequences within WCM lineages (bold) and between WCM lineages and outgroup species^a

GTR, general time reversible (model); ITS1, internal transcribed spacer region; WCM, wheat curl mite.

^aFor a definition of each lineage, see Figs 3–5.

p -distance among WCM sequences was 0.6% (SE = 0.3%) and ranged from 0% to 1.4%. This short ITS1 dataset was not very informative compared to the longer rDNA dataset that included ITS1 as well as sequences from the adjacent 5.8S and ITS2 regions. The longer dataset consisted of 10 aligned sequences of 758 bps representing nine sequences of WCM and one outgroup sequence. Within this alignment, 59 positions were variable. The mean uncorrected p -distance over all sequences (including the outgroup taxon) was 2.3% (SE = 0.3%) and ranged from 0% to 6.9%, whereas GTR distance ranged from 0% to 7.3%, and averaged 2.4% (SE = 0.3%). The mean p -distance among WCM sequences was 1.3% (SE = 0.3%) and ranged from 0% to 2.5%, whereas GTR distance ranged from 0% to 2.6% and averaged 1.3% (SE = 0.2%). Pairwise comparisons of the ITS distances within and between WCM lineages and between lineages and outgroup species are presented in Table 3.

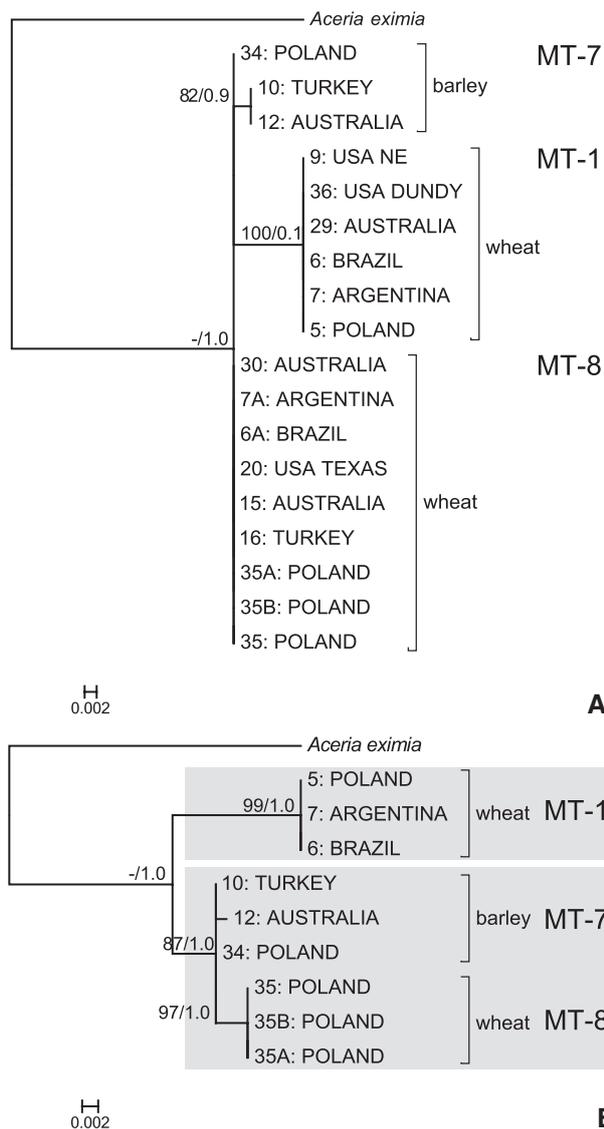

Figure 4 Maximum likelihood tree constructed using the TPM2 model for the ITS1 dataset (A) and ITS1, 5.8S and ITS2 dataset (B) of sequences from wheat curl mite populations in Europe, Australia, North America and South America. A concordant tree was obtained by Bayesian inference (BI), that produced the same topology. Statistical supports indicate ML/aLRT values/Bayesian posterior probabilities. Only statistical supports higher than 60/0.6 are indicated above branches. Populations of wheat curl mite (WCM) are numbered and numbers correspond to data in Table 1.

described WCM lineages (e.g. *Bromus* spp., *Elymus* spp.) in regions invaded by pestiferous WCM lineages.

The MT-1 lineage, which diverged by >13% (uncorrected p-distance) and >23% (K81 distance) in COI sequence from the two other invasive lineages, was shown here to be capable of colonising maize (Fig. 1) and bulbs of garlic, onion and tulip (Fig. 2) although on these hosts its population growth was significantly

slower than on wheat, the presumed preferred host. MT-1 colonised maize in this study after a wheat plant densely populated with mites was placed in contact with a clean maize plant, whereas in a previous study (Skoracka *et al.*, 2013) manual transfer of 15 mites from wheat to maize did not enable successful colonisation. MT-1 has now been shown to successfully colonise all 10 plant species (in three families) offered as hosts in bioassays and has spread to all five continents (viz. North and South America, Europe, Asia, Australia) surveyed in this study. The other invasive lineages identified here, viz. MT-7 and MT-8, were each present on several continents but were not recorded on or were not able to colonise plants outside the family *Poaceae* (Skoracka *et al.*, 2013). These latter two lineages are also more closely related to each other than to MT-1 based on DNA sequence data (Figs 3–5, and Tables 2 and 3). It is possible that MT-7 and MT-8 lineages may hybridise when encountering each other on wheat, although wheat may be an accidental host for MT-7 (see below). This assumption can be supported by the similarity of the nuclear ITS gene data (Fig. 4). Further sampling of these lineages throughout their ranges, as well as analyses of additional DNA markers (e.g. SSR or SNP) will be necessary to detect potential hybridisation among multiple WCM lineages.

MT-7 and MT-8 were recorded from three (Europe, Asia, Australia) and four (North America, Europe, Asia, Australia) continents, respectively. MT-7 was collected from wall barley in Poland, Turkey and Australia (Fig. 3) and colonised common barley in host-range testing of the Polish population (Skoracka *et al.*, 2013). However, the same host-range tests indicated that MT-7 could not colonise wheat. Thus it is possible that the record of MT-7 on wheat in Australia was accidental. Additional host-range tests on all MT-7 populations will be necessary to determine whether this lineage is restricted to *Hordeum* spp. hosts. MT-8 was collected from three distantly related *Poaceae* genera (viz. *Bromus* L., *Triticum* L., and *Zea* L.) but its host range has yet to be assessed experimentally.

All three pestiferous, invasive WCM lineages were represented in both Europe (Poland) and southwest Asia (Turkey), supporting the assumption made at the outset of this study that *A. tosichella* originated in Europe or adjacent areas of Asia and was spread globally from there, mainly through its association with cultivated cereal species. It is logical to further hypothesise that the modern (i.e. post-Columbian) invasion of the Americas and Australia by WCM mirrors a previous spread throughout pre-historic grain-producing regions of Eurasia and Africa although additional collections and phylogenetic analyses with additional genetic markers will be necessary to test this hypothesis. It may also be postulated, based on the presence of several lineages of *A. tosichella sensu lato* that

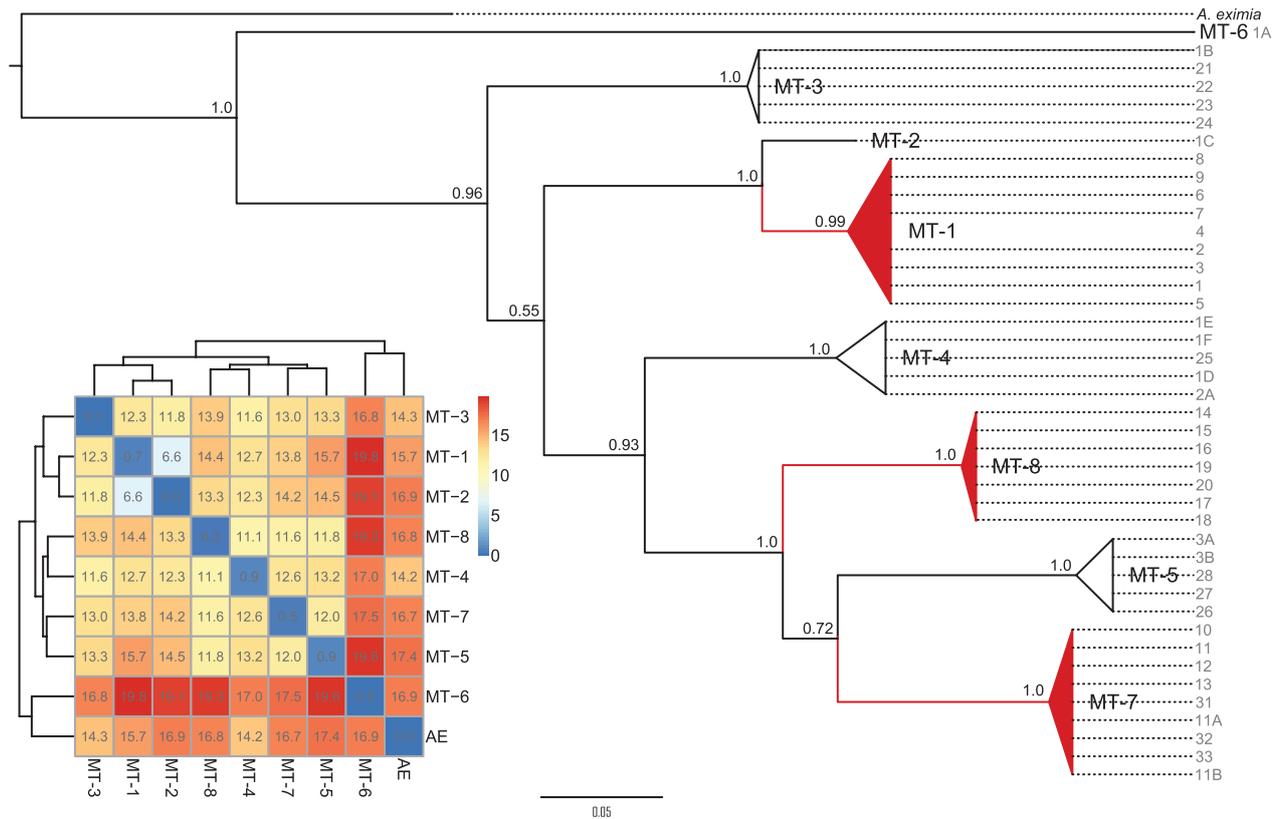

Figure 5 Bayesian inference (BI) tree constructed using the HKY + G model for the cytochrome c oxidase subunit 1 (COI) sequences of all currently known wheat curl mite (WCM) COI lineages and one outgroup species. Lineages from MT-1 to MT-7 have been distinguished in a previous study (Skoracka *et al.*, 2013) on the basis on molecular and host-specificity data. Each WCM lineage is represented by all known specimens. The lineages discussed in this study (see Fig. 3) are marked with red triangles. The labels correspond to sequence labels provided in Table 1. Statistical supports above branches indicate Bayesian posterior probabilities. Heat map represents pairwise uncorrected *p*-distances for COI gene.

utilise various wild grasses but not wheat (Skoracka *et al.*, 2013), that the progenitor of today’s *A. tosichella* utilised one or more related grass species prior to the domestication of wheat and other cereals.

Speciation of WCM due to pre-zygotic reproductive barriers appears to be underway in the European range (Skoracka *et al.*, 2013), including but not limited to separation by divergent host utilisation. Intercontinental invasion by a subset of WCM lineages is also likely to promote speciation of WCM due to geographic separation from non-invasive lineages remaining in Europe, as well as exposure of invasive populations to indigenous or other potential host species on invaded continents. Invasive, polyphagous WCM lineages could spread away from cereal-producing areas of their invaded ranges into areas dominated by such novel hosts and cause environmental concern in addition to economic damage (Marini *et al.*, 2011). The record of MT-1 in Australia on rescuegrass (*Bromus catharticus* Vahl), an introduced forage species from South America (Wu *et al.*, 2009), is an illustration

of this possibility. In addition to its broader host range on grasses, the ability of MT-1 mites to survive on bulbs of species such as garlic, onion, and tulip increases the potential for MT-1 movement between and within continents in comparison to the other, grass-specific WCM lineages whose survival off of green plants is very limited (G. Hein, unpublished data). This enhanced dispersal ability will likely lead to geographic isolation of some invasive MT-1 populations, away from other WCM lineages, and expose them to unique selection pressures.

All three invasive WCM lineages have been recorded in Australia and two of these three lineages have been recorded in North America, highlighting the global scale of this invasion. As with other mites, prevention of these invasions is hindered by the mite’s minute size and the ability of a single female to found a colony (Boubou *et al.*, 2010; Michalska *et al.*, 2010). The detection here of three different invasive WCM lineages in Australia, combined with earlier findings showing that WCM populations in Australia differed in their ability to transmit WSMV

(Carew *et al.*, 2009), also underscores the need for separate testing of the ability of different WCM lineages on all continents to transmit WSMV and other plant viruses.

Acknowledgements

We thank Zofia Banaszak (director of plant breeding centre DANKO) for permission to collect wheat, Mirosława Dabert (Molecular Biology Techniques Laboratory, Faculty of Biology, Adam Mickiewicz University [AMU]) for designing the primer 28Srev430, Urszula Sobczyńska (AMU, Poland) for help with laboratory work, Evsel Denizhan for providing three samples, the editor of *Annals of Applied Biology* and two anonymous reviewers for helpful comments that greatly improved the manuscript. The study was funded by the National Science Centre in Poland (Grants Nos. 2011/03/B/NZ8/00129 and 2011/01/N/NZ8/04540). The US portion of this project was partially funded by USDA NC-IPM (CSREES) Grant No. 2004-34103-14443 and by USDA-ARS Specific Cooperative Agreement no. 58-5440-7-334. A. S. and L. K. conceived and designed the study. A. S. performed the experiments. A. S., W. S., G. H. and R. F. carried out the molecular genetic studies. L. K., A. S. and W. S. analysed the data. B. R. and A. S. wrote the manuscript. L. K., W. S., G. H. and R. F. partially wrote methods and results. All authors critically revised the manuscript and read and approved the final manuscript.
