a large beginning, certainly. Also catalogued are collections of animal drawings and paintings, and manuscript letters of naturalists.

The catalogue is incomplete to the extent that many papers (thousands) not being bound are not here catalogued and yet are available either as separates or bound in the journals possessed by these various libraries. Limited space made this omission necessary. The catalogue is therefore, to that extent, not complete for the libraries included. This deficiency is pointed out by the compiler. The journals (an extensive list of them) are named in the catalogue, and the annotations indicate in each case the degree of completeness of the files.

In spite of the limitations indicated, the volume will be found a very important reference work for all who are interested in the literature of vertebrate taxonomy or vertebrate faunas. The price makes it out of the range of the average individual worker, but it should be made available in all zoology working libraries.

INDICATOR SIGNIFICANCE OF BRUSH LANDS FOR THE GROWTH OF WESTERN YELLOW PINE

A study of unusual interest and significance in the application of ecological principles to the solution of an economic problem has recently been completed.¹ It deals with the causes for the absence of western yellow pine in brush vegetation of various types that occur throughout the mountainous portions of northern Utah, eastern Idaho, and western Wyoming, and, in fact, form a much interrupted and fragmented belt whose center extends from the Gulf of California to west-central Montana. Many of these brush sites, especially in northern Utah and southern Idaho, lie immediately below the Douglas fir type (which is continuous) and would normally be expected to support yellow pine, since they have the same elevation as pine clad areas in other parts of the West. An attempt to improve the brush cover by the planting of pines during a 5-year period ended in failure and led to the present investigations. They were conducted with the idea of determining the feasibility of planting pines, and thus extending the natural range of the forest, and of discovering means whereby areas suitable for the growth of pine could be determined.

A study was made to determine the characteristics of climate and soil in the brush lands, especially those lying between northern Utah and southeastern Idaho, and to compare them with conditions prevailing where the pines grew naturally. Temperature, although a potent factor in determining distribution

¹ Baker, F. S., and C. F. Korstian, 1931. Suitability of brush lands in the intermountain region for the growth of natural or planted western yellow pine forests. *U. S. Dept. Agri. Tech. Bull.*, 256.

of species in mountainous regions, does not explain the peculiarities of the pine on both sides of the brush-land belt. There is apparently a broad zone extending from the base of the near-by forested mountains to intermediate elevations covered with brush. Nor are there notable differences in total annual precipitation, which obviously is not the controlling factor in the plant distribution. The distribution of the precipitation during the summer months in the brush lands is, however, very different from that either to the north or the south. "May precipitation within the temperature zone suited to western yellow pine is ample for the reproduction of this species. In the pinelands to the south, the July and August precipitation, which greatly exceeds that in the brush lands, is ample for the reproduction of western yellow pine. In the intervening brush lands the light character and brief duration of May rain, coupled with the extremely dry June that quickly follows, prevents the establishment of the reproduction in the early spring. Deficiencies in July and August precipitation, combined with the fact that the rainfall usually culminates in August shortly before the early autumn frosts occur, make it impossible for the species to reproduce."

Although the distribution of the rainfall determines the general limits of the pine lands, the details of its boundaries are chiefly the results of local differences in soils. In general, the lighter types of soil are more favorable to the pines and especially so near the edge of their range, the pines spreading far from the main bodies of forest on sandy soils and along streams. The brush lands, in general, are characterized by calcareous, heavy, fine-grained soils and are prevailingly unsuitable for the growth of the pine. Unfortunately, data on climatic and edaphic factors in the brush lands and forests of this vast area are meager, but those available are convincingly presented.

In a second line of study, seedlings of the pine were transplanted under different conditions in the brush-land areas, since it is well known that planted stands often develop normally in regions where natural regeneration is impossible. Plantations were established in the brush belt in central, western, and northern Utah and also in southern Idaho. The effects on the transplants of soil moisture, soil texture, rate of evaporation, and shade were all carefully considered as well as injury by rabbits.

It was concluded that the establishment of artificial stands by planting is rendered extremely difficult by the same factors of rainfall that operate so powerfully against the natural reproduction of this species that the pine can not naturally invade the permanent brush lands. In fact, success in planting generally occurred only on sites with unusually favorable water content, and conspicuous success was attained only in seasons of exceptionally heavy spring rainfall. Moreover, suitable sites are not easily selected in average years, for they generally bear such a luxuriant cover of brush that failure of the seedlings due to shade is almost certain.

Attention was thus naturally directed to the use of the various native shrubs as indicators of desirable planting sites. Their natural succession,

root development, and leaf characters were extensively studied. A brief statement of the succession on wet and dry lands, and also the effect of fire is given. It is emphasized that the brush lands are the climatic climax and not subclimax vegetation resulting from repeated fires. Excellent sketches of the root systems of the pine and 21 of the most important shrubs are given, illustrating four general root types, *viz.*: deeply rooted species with taproots and practically no feeding roots in the upper layers; species with widely spreading rhizomes with a shallow network of roots and a deep-feeding root system; generalized root system; and 2-storied systems with practically no feeders in the intermediate soil layers.

In selecting planting sites not only soil moisture and root competition but also the degree of shade must be considered. A study of the vegetation on the ground enables all three factors to be evaluated with a fair degree of accuracy. The presence of shallow rooted species absorbing mainly in the surface soil indicates that the pines must be planted in direct competition with the native vegetation. Such sites are unsuitable for planting. "The best results can be obtained with plantations on sites where absorbing roots of the native vegetation are found at depths below 2 feet and where the trees can safely be placed close to the north side of the bushes where the shade will serve to reduce evaporation and transpiration. Such sites are likely to be naturally severe, as deep-feeding shrubs tend to occupy dry sites. Therefore, in most cases such sites should be selected for forest plantations only when they are otherwise naturally suitable." "If the native vegetation can be removed before planting, sites which originally supported a vegetation composed of shallow-rooted species will prove the most satisfactory. . . ."

The study of leaf characters included leaf size, structure, water content, relative transpiration, and sap density. These were made with the purpose of extending the usefulness of the native shrubs as indicators of planting sites by showing which deeply rooted species, as heavy users of water, may indicate areas where there is sufficient water available for western yellow pine. Although "there is no satisfactory way of summarizing all these factors so that their resultant effect is evident, for their relative importance is still largely unknown," yet with the aid of these criteria (including root characters and crown density) it is possible to select suitable sites for planting in the brush lands. A species should not be planted on any site where the native vegetation possesses uniformly higher sap densities than those generally maintained by the planted species during the dry season. "Contrary to an earlier belief, the brush lands are fundamentally unsuited to the natural reproduction of western yellow pine. . . . Moreover, there is no evidence that stands artificially established will maintain themselves or spread naturally as originally expected." "Only a portion of the brush lands can be classed as suitable planting sites, and the best sites, covered with deep-rooted, thin-foliaged shrubs on northern exposures, are rare." Cleared or burned sagebrush areas may show fair success; the remainder of the sites are inferior.

Hence, extensive planting in the permanent brush lands of the intermountain region is not justified.

This extensive research adds much to the ecology of the great intermountain region and is an excellent contribution to the important subject of plant indicators.

SOUTHERN WHITE CEDAR¹

This publication should be of interest not only to the forester but to the ecologist as well. It is composed of three principal parts. In the first part *Chamaecyparis thyoides* is discussed from every angle, including its characteristics and management as a timber tree. In the second part, the authors present a mass of much needed information concerning the economic importance of this little known species. The third part is of particular interest to the forester. Here are given yield, volume and taper and form tables. For the ecologist, however, the first eighteen pages are of particular interest. In these few pages the authors have succeeded in condensing a wealth of information. Condensed though it is, it is not presented in the form of a summary, and makes pleasant reading.

In the first part are included such topics as the distribution of this species in the United States, the climatic and edaphic conditions that control the distribution of the species and the biotic factors that influence the natural reproduction of the white cedar. It is of particular interest to note that birds and rodents consume but little of the seed crops and that reproduction depends largely on the proper conditions for the germination of the seeds and the survival of the seedlings. It seems that the main reason that this species does not cover larger areas is that its seeds are often imbedded in the litter and peat of the forest floor, where they remain dormant for long periods of time. Apparently it is the moisture content in the upper layers of the soil that serves as a controlling factor for the regeneration of this species. During the summer and early autumn many seedlings die for lack of moisture, while in the winter and spring, many seedlings are drowned because of prolonged flooding. Only on recent burns in water-filled swamps and on recently cut-over lands and clearings do the seedlings of the white cedar succeed in becoming established. Although the seedlings of this species can tolerate much shade, they are, nevertheless, frequently killed by the dense shade produced by the competing vegetation in the swamps. On cut-over areas, where the competitors have been removed, the white cedar seedlings come in dense stands often as many as 100,000 to the acre and sometimes even as many as 2,000,000 to the acre. On 8-year-old cuttings, as many as 30,000 seedlings to the acre were counted.
