Air Line Pilots Association, Spring, Texas

Abstract: Bird-aircraft collisions (bird strikes) are an increasing safety and economic concern to the USA civil aviation industry, costing over $400 million each year. One approach to reducing risks associated with strikes is to require commercial aircraft components to meet certain standards of safe performance in the event of a bird strike. The Federal Aviation Administration has developed airworthiness standards for airframes, windshields and engines using a single 4-lb (1.82-kg) bird mass as the maximum that must be tested (with the exception of a single 8-lb bird for the empennage, 6-lb bird for certain mid-sized engines that may be developed in the future, and a 6-lb bird for certain large-intake engines on aircraft such as the Boeing 777). Because of concern within the aviation industry that populations of certain flocking bird species weighing more than 4 lbs, such as Canada geese (Branta canadensis), have increased dramatically, discussions are underway in the USA and Europe regarding the need to revise 4- and 8-lb test standards to heavier body masses or to include multiple strikes. To help clarify this issue, we surveyed the avian literature and determined that 36 and 14 of the approximately 650 bird species that nest in North America (north of Mexico) have average body masses (for at least 1 gender) greater than 4 and 8 lbs, respectively. Of the 31 species for which population trend data were available, 24 (77%) showed population increases over the past 20-40 years, 2 showed declines, and the other 5 were stable. Thirteen of the 14 species with mean body masses over 8 lbs showed population increases. At least 261 strikes with >4-lb birds caused substantial damage to civil aircraft in the USA, 1990-2001. Furthermore, multiple birds were involved in 31% of the strikes with >4-lb birds and 40% of the strikes with >8-lb birds. Therefore, we conclude that airframe, windshield, and engine standards, as well as proposals to allow high-speed (>250 knot) operations below 10,000 feet, should be reevaluated to address the threat posed by increased populations of large flocking birds. Finally, because most critical aircraft components are not designed to withstand strikes by birds greater than 4 lbs, wildlife biologists who work at airports should increase efforts to detect, remove and disperse these large birds from airport environments.

Introduction  
Aircraft collisions with birds (bird strikes) are a serious economic and safety problem. Cleary et al. (2002) estimated wildlife collisions (97.5% involving birds) cost the civil aviation industry in the USA over $400 million/year, 1990-2000. Allan (In Press) projected that bird strikes annually cost commercial aviation over $1.2 billion worldwide in 1999-2000. At least 138 people died worldwide as a result of bird strikes from 1990-2000 (Thorpe 1996, 1998; Richardson and West 2000; Dolbeer, unpublished data). About 71% of bird strikes to civil aircraft occur below 500 feet during takeoff and landing (Cleary et al. 2002). Thus, implementation of integrated management programs to reduce bird populations in airport environments is essential to minimize bird strikes (Cleary and Dolbeer 1999). However, given the diversity and mobility of avian species, programs to manage bird hazards at airports will never exclude all birds from aircraft movement areas (e.g., Dolbeer 1999) and will do nothing to prevent strikes outside the airport environment. Therefore, a second critical component to reduce the hazards and economic costs of bird strikes is the development of airworthiness standards for airframes, windshields, and engines that ensure aircraft can operate safely in the event of a bird strike.

The Federal Aviation Administration (FAA) has developed airworthiness standards for airframes and windshields of transport aircraft (>19 passenger seats) using a single 4-lb (1.82 kg) bird as the maximum-sized mass that must be tested (with the exception of 8 lbs [3.64 kg] for the empennage). Standards for commuter aircraft (10-19 seats) are less stringent (Table 1). The maximum mass required for turbine-engine testing is a single 4-lb bird for most engines currently in service, a single 6-lb bird for certain mid-sized engines that may be developed in the future, and a single 8-lb bird for certain large-intake engines used on new wide-bodied aircraft such as the Boeing 777. The engine does not have to keep operating after a 4-, 6- or 8-lb bird ingestion to pass these standards; rather, the engine must contain the damage, not catch fire, and be capable of shut-down (Table 1). MacKinnon et al. (2001) provide a more detailed discussion of airworthiness standards related to bird strikes. Aggressive programs by natural resource and environmental agencies and organizations during the past

30 years (e.g., pesticide regulation, expansion of wildlife refuge system), coupled with land-use changes, have resulted in dramatic increases in populations of many wildlife species in North America (Dolbeer 2000). In addition, certain of these wildlife species that are a proven threat to aviation, such as Canada geese (Branta canadensis) (Cleary et al. 2000), have adapted to urban environments (Smith et al. 1999), making the risk of wildlife strikes at airports much greater. Because of concern within the aviation industry with populations of large bird species, discussions are underway in North America (FAA and Transport Canada) and Europe (Joint
Aviation Authorities) regarding the need to revise the 4- and 8-lb test standards to heavier body masses or to include multiple strikes by these large birds as part of the standards (e.g., MacKinnon et al. 2001, Eschenfelder 2001).

To help clarify this issue, we surveyed the avian literature to determine the number, flocking characteristics, and population status of bird species with body masses greater than 4 and 8 lbs that inhabit North America. In addition, we determined the reported number of single and multiple bird strikes involving these species for civil aircraft in the USA, 1990-2001. Our goal is to provide objective data on the numbers, population trends, flocking characteristics, and strike patterns for these large bird species to aid regulatory bodies, engineers, and biologists in developing standards and strategies to reduce the costs and hazards of bird strikes.

METHODS

Alsp (2001) was our primary reference source to initially screen, from the approximately 650 bird species that nest in North America (USA, Canada and Caribbean Islands), those species having a mean body mass approximating 4 lbs or more. This list was refined by examining data on avian body masses from Dunning (1993) and other sources. Those species included in the final list had a mean body mass >4.0 lbs for at least one gender, or if data were unavailable by gender, a mean body mass >4.0 lbs for unknown gender.

We obtained population data (numbers of birds and mean annual % change in numbers) for each species from various sources such as the North American Breeding Bird Survey (BBS), Christmas Bird Counts (CBC), North American Waterfowl Survey reports, North America Waterbird Conservation Plan, and the scientific literature. For BBS or CBC data, populations were classified to be increasing or decreasing if a significant (P < 0.05) mean annual percent change was detected for the years considered (generally 1966-2000 for BBS data; 1959-1988 for CBC data; Sauer et al. 1996, 2001). For other species, we calculated the mean annual percent change from a baseline year (earliest year [1959-1987] for which a reliable population estimate was available) and the most current (1994-2001) population estimate (Belant and Dolbeer 1993). Sources of information and scientific names for each species are listed in Appendix 1.

We subjectively classified the social behavior of each species relevant to bird strikes as strongly flocking, limited flocking, or generally solitary based on our general knowledge of the species and discussions among ornithologists. We also classified each species as soaring or non-soaring. Finally, we determined the number of reported strikes to civil aircraft in the USA involving these species, 1990-2001 (Cleary et al. 2002, S. E. Wright, U.S. Department of Agriculture, unpublished data). We also noted for each reported strike event whether a single bird or multiple birds were struck and the degree of damage.

RESULTS

Thirty-six species, about 6% of the approximately 650 species that breed in North America, had mean body masses >4 lbs for at least 1 gender (Appendix 2). Of the 31 species for which a population trend could be estimated, 24 (77%) indicated increases, 2 (6%) indicated declines, and 5 (16%) were stable (Table 2). All 13 (100%) of the 14 species with body masses above 8 lbs for which a population trend could be estimated indicated population increases.

Twenty-four (67%) of the 36 species exhibit strong flocking behavior, 9 (25%) exhibit limited flocking behavior, and only 3 (8%) exhibit solitary behavior (Table 2, Appendix 3). Five (14%) of the species regularly exhibit soaring behavior.

Sixteen of the 36 species were not involved in a reported strike with civil aircraft in the USA, 1990-2001 (Appendix 3). The 20 species reported as struck were involved in 1,568 strikes of which 789 (50%) indicated damage and 261 (17%) indicated substantial damage to the aircraft. Multiple birds were involved in 431 (31%) of the reported strikes. The 9 struck species with body masses >8 lbs were involved in 1,062 strikes of which 549 (52%) indicated damage and 167 (16%) indicated substantial damage. Multiple birds were involved in 417 (40%) of the strikes with >8-lb species. Sixteen (80%) of the 20 struck species with body masses >4 lbs have exhibited population increases; 9 (100%) of the species with body masses >8 lbs showed population increases (Table 3). Eighteen of the 20 struck species exhibit strong (13) or limited (5) flocking behavior.

DISCUSSION

Populations of most large (>4 lb) bird species in North America, including at least 13 of the 14 species with masses >8 lbs, have shown substantial increases during the past 20-40 years. Although some of these species are unlikely to be struck by aircraft, species such as Canada and snow geese, turkey vultures, great blue herons, bald eagles, and sandhill cranes have been struck numerous times during the past 12 years. Of significance is the fact that 31% of the >4-lb bird strikes and 40% of the >8-lb bird strikes involved multiple birds. We also note that 56% the 33,500 bird-strike reports in the FAA Wildlife Strike Database, 1990-2000, list the species struck as unknown (Cleary et al. 2002). Furthermore, an estimated 80% of strikes to civil aircraft in the USA go unreported (Cleary et al. 2000). Thus, the number of strikes reported for large (>4 lb) species (Appendix 3) should be considered an index and not an actual measure of strike rates. Undoubtedly, there have been many strikes with >4-lb birds (including some of the 16 species with no strikes recorded) that either have not been reported or reported as unknown species.
Our analysis clearly indicates that aviation regulatory and industry groups need to reexamine existing airworthiness standards with regard to bird-strike tolerances. Many of the regulations have not been revised since the 1970s when large-bird (4+ lbs) populations were much lower. Of particular concern is that existing standards for transport aircraft regarding large birds (in most cases 4 lbs being the maximum tested) do not consider multiple-bird strikes into a single engine or multiple engine ingestions. Yet, our data for 1990-2001 indicate 31% of strikes with >4-lb birds and 40% of strikes with >8-lb birds have involved multiple birds (see also Budgey and Allan 1999). The fact that current large-bird standards for engines only require that the damage be contained and that the engine be shut down safely has serious implications for multiple-bird strikes involving 2 engines. Such an incident occurred with a Boeing 707 aircraft that crashed at Elmendorf Air Force Base, Alaska after striking a flock of Canada geese during take off in 1995 (Cleary and Dolbeer 1999). Over 80% of transport aircraft in operation by 2010 will have only 2 engines (Dolbeer 2000). Although beyond the scope of this paper, detailed analysis of data from the long-term bird-strike databases that are now available (e.g., Cleary et al. 2000) should be invaluable in objectively guiding decisions regarding bird-strike airworthiness standards for transport, commuter and general-aviation aircraft (e.g., Martindale and Reed 1998).

Although revisions in airworthiness standards may be needed in response to increased populations of large flocking and soaring birds, existing aircraft and engines certified under current (single 4-lb bird) standards will remain in service for many years (Alge 1996). Furthermore, even if standards are revised and engineering improvements made, it will be impossible to completely “bird-proof” engines and airframes against high-speed collisions with birds of large mass. For example, a 4-lb bird struck by a transport aircraft going 150 knots at lift-off generates about 14,000 lbs of impact force (MacKinnon et al. 2001). Thus, it is imperative that aviation regulatory agencies in North America and elsewhere develop and maintain rigorous standards for bird hazard management programs at airports that emphasize the threat posed by these large birds and the need to minimize their presence in the airport environment (Cleary and Dolbeer 1999, Dolbeer et al. 2000). The deployment of bird-detecting radar systems to alert pilots and Air Traffic Control personnel may also prove useful in avoiding strikes with large flocking birds, especially during periods of migration (Kelly et al. 2001, Blokpoel and MacKinnon 2001).

As a final point, proposals to allow commercial aircraft to use high-speed (over 250 knot) operations below 10,000 feet to facilitate air traffic flow (National Transportation Safety Board 1999) should be reevaluated in light of increased populations of large-mass birds. Because of a fundamental relationship between energy (e), mass (m) and velocity (v) expressed in the equation 
\[ e = \frac{1}{2} mv^2, \]
aircraft velocity is even more critical than bird mass in determining the energy imparted to an aircraft by a strike. For example, a 20% increase in bird mass results in a 20% increase in energy on impact whereas a 20% increase in aircraft velocity results in a 44% increase in energy imparted. An incident in which a Boeing 727 was heavily damaged after striking 3-5 snow geese at 6,000 feet during a high-speed departure from a Houston, Texas airport in January 1998 confirmed the dangers to aircraft of high-speed impacts with large birds (Cleary and Dolbeer 1999).

ACKNOWLEDGEMENTS
This research was supported by the FAA, William Hughes Technical Center, Atlantic City, New Jersey under agreement DTFA03-99-X-90001. Opinions expressed in this study do not necessarily reflect current FAA policy decisions regarding the control of wildlife on or near airports. We appreciate the support and advice of FAA employees S. Agrawal, E. C. Cleary, and M. Hoven. We gratefully acknowledge the assistance of G. A. Baldassarre, S. C. Barras, G. E. Bernhardt, B. T. MacKinnon, J. L. Seubert, R. J. Sowden, and R. A. Siehn who provided body mass and population data and advice on the manuscript. S. E. Wright assisted with the analysis of bird strike data.

*MAPC = Mean annual percent change for years indicated based either on North American Breeding Bird Survey estimate or by calculating MAPC from estimated population in first and last year covered (Bellant and Dobber 1993).

+a Most recent population estimate for most species represents adult breeding population and does not include subadult birds.

*b Body mass presented is for "greater" subspecies, "lesser" subspecies mean body mass = 6.05 lbs.
Appendix 3. Flocking and soaring behavior for 36 species of birds in North America that have mean body mass for at least 1 gender >4 pounds ranked by number of reported strikes to civil aircraft in USA from 1990-2001 involving these species.

</tbody>
</table>

a Strong flocking = Birds normally associate in dense flocks while feeding, traveling or nesting; Limited flocking = Birds often found in small groups while soaring, migrating, feeding or breeding; Solitary = Birds normally feed and travel as individuals; Soaring = Birds typically soar while searching for food, often in loose flocks or "kettles" with other members of same species.

b Aircraft incurs damage or structural failure which adversely affects the structure strength, performance or flight characteristics of aircraft and which would normally require major repair or replacement of the affected component (excluded are: bent fairings or cowlings; small dents or puncture holes in skin; damage to wing tips; antenna, tires or brakes; engine blade damage not requiring blade replacement, International Civil Aviation Organization 1989).

c A total of 25 strike reports did not indicate whether or not multiple birds were involved: sandhill crane (1), Canada goose (6), brown pelican (1), great blue heron (2), turkey vulture (4), unidentified geese (10), unidentified vultures (1). These reports were excluded from total strikes when calculating percent of strikes involving >1 bird.

d Assuming all unidentified swan, pelican, eagle and goose strikes were with birds >8 lbs.
