Abstract
Herbaceous vegetation comprises the main habitat type in cool-season grasslands and can be managed by various methods. We compared changes in plant communities and bird and mammal use of grasslands that were not managed, managed by mechanical methods (mowing), or managed by chemical methods (plant growth regulator). This 1-year study was conducted from May through October 2003 in Erie County, Ohio. Twelve circular 1.5 ha plots were established: 4 were not managed, 4 were mowed to maintain vegetation height between 9–15 cm, and 4 were sprayed with a plant growth regulator and mowed when vegetation exceeded 15 cm. We monitored vegetation growth, measured plant community composition, and observed all plots for wildlife activity each week. Vegetation in unmanaged plots was taller and denser ($P < 0.001$) than vegetation in mowed and growth regulator plots. Plant community characteristics differed among study plots ($P < 0.001$); managed plots had higher grass cover and lower woody cover than unmanaged plots. We observed more ($P < 0.001$) total birds per 5-minute survey in unmanaged than mowed or growth regulator plots. We observed more ($P < 0.001$) white-tailed deer (Odocoileus virginianus) in mowed plots than either control or growth regulator plots. We captured 13 small mammals in unmanaged plots and no small mammals in managed plots. Applying the plant growth regulator was not a cost-effective alternative to mowing for managing vegetation height in our study. Vegetation height management practices altered plant communities and animal use of grassland areas and thus might be useful for accomplishing species-specific habitat management objectives.

Key Words: grassland birds, growth regulator, mowing, white-tailed deer

INTRODUCTION

Grassland habitats in the United States, regardless of the ecotype, are often managed in a prescribed way (e.g., mowing, prescribed burning, grazing) to maintain the integrity of the physical characteristics desired for that habitat type. These management methods can be applied to hayfields, pastures, rangelands, airfields, old-fields, and other human-altered systems (Bollinger 1995; Norment 2002). Eastern grassland habitats are typically dominated by introduced cool-season grasses (e.g., tall fescue [Lolium arundinaceum] Schreb. S. J. Darbyshire), timothy [Phleum pratense L.], cool-season forbs and legumes (e.g., clovers [Trifolium spp. L.]), and few native plants (Vickery and Dunwiddie 1997; Norment 2002). These
grassland areas are maintained in an early successional stage through disturbance, typically by a method to maintain vegetation at a desired height.

Mechanical mowing is the most widely used tool for managing vegetation height in humid grassland areas. However, mowing grassland areas during the breeding season can reduce reproductive success of grassland birds (Frawley and Best 1991; Bollinger 1995). Other tools, such as herbicides and plant growth regulators, might be useful for managing vegetation growth and structural characteristics (Morré 1993; Reynolds et al. 1993). Using selective herbicides might allow land managers to alter vegetation structure and composition in cool-season grasslands by removing or favoring (e.g., by removing competition) certain types of plants (Washburn et al. 2002).

Our study objectives were: 1) to compare the effectiveness of management techniques for managing vegetation height and altering plant community characteristics and 2) to compare bird and mammal use of cool-season grasslands that were not managed, managed by mechanical methods (mowing), or managed by chemical methods (plant growth regulator).

**MATERIAL AND METHODS**

**Study Site**

The study was conducted from May 2003 through October 2003 at the National Aeronautics and Space Administration’s Plum Brook Station (PBS), Erie County, Ohio (lat 41°37’N, long 82°66’W; elevation 198 m). Mean annual precipitation is 863 mm · y⁻¹ and the average daily temperature during summer is 22.2°C (Robbins et al. 2002). Habitat within PBS consists of dogwood (Cornus spp. L., 39%), grasslands (31%), open woodlands (15%), mixed hardwood forests (11%), and roads and buildings (4%) (Rose and Harder 1985).

In May 1999, 8 circular 1.5-ha plots were established by clearing and then mowed 2–4 times a month during the growing season in 1999–2002 as part of a study examining effects of vegetation height on wildlife use of grassland areas (Seamans et al. 2007). For this study, 4 of these plots were randomly selected to be mowed with the remaining 4 to be treated with a plant growth regulator (herbicide mixture) and mowed as needed. In addition, 4 additional plots in unmanaged herbaceous fields were selected as control plots. Plant communities in the plots consisted of a variety of grasses, forbs, and legumes.

**Vegetation Height Management**

At the start of the study, the 4 mowed and 4 growth regulator plots were mowed to a height of 9 cm. Throughout the study, when the mean maximum vegetation height of 15 cm was exceeded in a mowed or growth regulator plot we mowed the plot to a height of 9 cm.

A plant growth regulator (herbicide) mixture was applied to the regulator plots twice, on 14 May 2003 and 28 July 2003. The plant growth regulator mixture consisted of imazapic at 0.05 kg active ingredient (ai) · ha⁻¹ (Plateau herbicide, BASF Corp, Research Triangle, NC), dicamba at 0.23 kg ai · ha⁻¹ plus diflufenzopyr at 0.08 kg ai · ha⁻¹ (Overdrive herbicide, BASF Corp, Research Triangle, NC), and non-ionic surfactant at 2.3 L · ha⁻¹. The sprayed plots were not mowed during the week following plant growth regulator application.

**Vegetation Measurements**

Plant community characteristics in all plots were measured weekly from 5 May 2003 to 14 October 2003. Each week, 10 sample points were randomly selected in each of the 12 circular 1.5-ha plots. At each sample point, we measured the maximum vegetation height by placing 2, 1-m sticks vertically 1.5 m apart with a string connecting the sticks. We adjusted the height of the string parallel to the top of the tallest plant under the string and recorded the distance from the string to the ground (cm). We also measured two visual obstruction readings (VOR) at each sample point (Robel et al. 1970). Plant cover by species group (e.g., grass) was sampled at 6 set points along the 1.5-m string used to measure vegetation height. The plant immediately below each sample point was classified into 1 of 9 species groups.

**Animal Observations**

**Birds.** Bird observations were conducted 2 days per week from 8 May 2003 to 16 October 2003 starting at randomly chosen plots and times from sunrise to sunset. We observed each circular 1.5-ha plot from a fixed point within 30 m of the plot for 5 minutes once each day. The number of birds observed on the ground or on a plant within the plot, flying and feeding over the plot, or flying over the plot was recorded by species and activity.

**Mammals.** We estimated white-tailed deer (Odocoileus virginianus) use of the circular 1.5-ha plots by conducting 2 sets of 3-minute observations (i.e., surveys) once every 2 weeks from 15 May 2003 to 16 October 2003. We started the first survey 30 minutes before sunset and used binoculars to count deer in or within 1 m of each plot. We started the second survey 30 minutes after sunset and used a Forward-looking Infrared (FLIR) unit (PalmIR 250, Raytheon Commercial Infrared, Dallas, TX) to count deer.

Small mammal abundance was quantified by snap trapping all circular 1.5-ha plots for 3 nights in April of 2003 and also for 2 nights in October of 2003. A 50 × 100m trapping grid centered in each plot was used with modified rat traps placed at 10-m intervals (50 traps · plot⁻¹). Capture rate was defined as the number of animals caught · 100 adjusted trap nights⁻¹ (Nelson and Clark 1973). The National Wildlife Research Center Institutional Animal Care and Use Committee approved procedures involving birds and mammals (QA-1038).

**Statistical Analyses**

Vegetation data were non-normally distributed and could not be transformed satisfactorily. We used Kruskal-Wallis tests (Zar 1996) to compare plant community characteristics among vegetation management treatments. The percentage of times mowed and growth regulator plots were mowed was compared using a comparison of proportions test (Zar 1996). We wanted to consider only birds actually associated with (e.g., using) the plots and thus removed birds with the “flying” activity codes from the data prior to analyses. The bird and deer observation data were not normally distributed and could not be transformed satisfactorily. Therefore, we compared bird and...
deer use among treatments using Kruskal-Wallis tests (Zar 1996). We considered differences significant at \( P \leq 0.05 \). Data are presented as mean ± 1 standard error.

## RESULTS

### Plant Communities

Mean maximum vegetation height differed \(( P < 0.001)\) among the managed and unmanaged plots. Vegetation in the unmanaged plots (60.5 ± 0.8 cm) was taller than vegetation in the mowed (17.3 ± 0.1 cm) and growth regulator plots (16.9 ± 0.2 cm). Similarly, the mean VOR in unmanaged plots (27.8 ± 0.5 cm) was greater \(( P < 0.001)\) than the similar mowed (5.7 ± 0.1 cm) and growth regulator (5.3 ± 0.1 cm) plots. We found no difference \(( P = 0.30)\) in the percentage of times that mowed (77.6 ± 5.0 %) or growth regulator (67.1 ± 7.9 %) plots were mowed.

Vegetation height management practices altered the plant community composition of mowed and growth regulator plots compared to the unmanaged plots (Table 1). Mowed and growth regulator plots had more grass \(( P \leq 0.001)\) than unmanaged plots. Forbs and legumes were reduced \(( P \leq 0.001)\) in the growth regulator plots following 1 and 2 applications of the growth regulator mixture. Unmanaged plots contained more woody plants than either mowed or growth regulator plots (Table 1).

### Animal Responses

**Birds.** We observed more \(( P < 0.001)\) birds per 5-minute survey on the ground and perched on vegetation in unmanaged (3.0 ± 0.3) than mowed (1.5 ± 0.2) and growth regulator (1.5 ± 0.3) plots. We observed a total of 30, 18, and 19 bird species on the ground or on plants in the unmanaged, mowed, and growth regulator plots, respectively. Fifteen bird species were observed in the unmanaged plots but not in the managed plots. Red-winged blackbirds \((Agelaius phoeniceus)\), American robins \((Turdus migratorius)\), American goldfinches \((Carduelis tristis)\), and European starlings \((Sturnus vulgaris)\) were the birds we most frequently observed (26.3 %, 15.7 %, 11.2 %, and 10.5 % of the total individuals seen, respectively) using the study plots.

Species-specific variation occurred in bird use of unmanaged and managed vegetation (Table 2). Red-winged blackbirds, American goldfinches, field sparrows \((Spizella pusilla)\), and song sparrows \((Melospiza melodia)\) used unmanaged vegetation plots more than plots where vegetation management practices (mowing or chemical) were implemented, whereas European starlings and American robins were observed primarily in managed plots.

**Mammals.** We observed more \(( P < 0.001)\) white-tailed deer (sunset and FLIR survey combined) in mowed plots (4.3 ± 0.5) than either unmanaged control (2.2 ± 0.6) or growth regulator (1.6 ± 0.3) plots. Overall, we observed more \(( P < 0.001)\) deer in the plots in July (4.2 ± 0.7), September (4.8 ± 1.3), and October (3.0 ± 0.5) than in May (0.8 ± 0.3).

We captured a total of 13 small animals from 6 species in the unmanaged plots in April of 2003 (0.5 captures · 100 trap nights\(^{-1}\)) and October of 2003 (1.7 captures · 100 trap nights\(^{-1}\)). We captured no small mammals (0.0 captures · 100 trap nights\(^{-1}\)) in either the mowed or growth regulator plots.

### DISCUSSION

The plant growth regulator (herbicide mixture) was expected to reduce the growth of cool-season grasses and kill broad-leaved forbs and legumes. Periodic observations of the vegetation within the growth regulator plots showed that the plant growth regulator reduced the growth and suppressed seedhead formation in cool-season grasses (e.g., tall fescue) for 6 to 8 weeks following application. Seedhead suppression and reduced growth of some grasses were likely due to the application...
of the imazapic component of the plant growth regulator mixture (Yelverton et al. 2000). However, as the growing season progressed, other grasses that apparently were not affected by the plant growth regulator (e.g., smooth brome [Bromus inermis Leyss.]) continued to grow, causing the overall vegetation height to exceed the prespecified height of 15 cm and resulting in the plots being mowed. The dicamba and diflufenzopyr components of the plant growth regulator mixture likely reduced forbs and legumes (e.g., clovers, common dandelion [Taraxacum officinale G.H. Weber ex Wiggers]) in growth regulator plots (Grossman et al. 2002; Lym and Deibert 2005).

Although growth regulator plots were mowed 10% less frequently than mowed plots, this reduction did not offset the cost of herbicides and application. Costs to apply the plant growth regulator were approximately $92.5 · ha⁻¹ or $1 110 to spray the 4, 1.5-ha plots twice. Costs to mow were $10 · ha⁻¹ or $60 to mow 4, 1.5-ha plots. A 10% reduction in mowing is equivalent to 2 fewer weeks of mowing, resulting in a $120 savings. Therefore, spending $1 110 to apply chemicals did not reduce mowing enough to offset spraying costs but actually cost $990 more than the cost of mowing the plots.

Plant community characteristics, such as the density and structure of vegetation, have been shown to influence bird use of grassland areas (Frawley and Best 1991; Norment 2002). Managing vegetation height, either through mowing or applying a growth regulator, resulted in species-specific patterns of bird use that differed from unmanaged plots. American robins and European starlings were observed almost exclusively in managed plots, whereas red-winged blackbirds, American goldfinches, song sparrows, and field sparrows were observed mostly in the unmanaged plots. These birds were likely using the taller, denser vegetation and woody plants in the unmanaged plots (King and Savidge 1995; Warren and Anderson 2005).

Vegetation height management influenced the use of plots by mammals. During our study, we captured small mammals only in the unmanaged plots. Other researchers have reported that mowing vegetation appears to discourage small mammal use of grasslands (Lemen and Clausen 1984; Edge et al. 1995). Approximately twice as many white-tailed deer were observed in the mowed plots than in the unmanaged and growth regulator plots. Broad-leaved herbaceous plants, such as clovers and common dandelion, constitute large portions of deer summer diets (Korschgen et al. 1980; Rose and Harder 1985). The large reductions in forb and legume cover following the growth regulator applications resulted in much less forage available in the regulator plots. Thus, less white-tailed deer use might be due to the reduction in preferred forage plants.

MANAGEMENT IMPLICATIONS

Managing vegetation height altered plant community characteristics and wildlife use of the study plots. Land managers should use different vegetation height management methods, depending upon their management goals for cool-season grasslands. Reducing wildlife use of cool-season grasslands might be accomplished by intensive mowing and applying a broadleaf-selective herbicide. In contrast, not managing vegetation height in cool-season grasslands should result in more bird and mammal use. However, disturbance of cool-season grasslands through mowing, burning, or grazing every few years will likely be necessary to deter woody plant invasion.

Plant growth regulator application is not a cost-effective alternative to mowing for managing vegetation height in cool-season grasslands that consists of a variety of plant species. Additional research is needed to determine if this method of vegetation height management would be cost-effective in monotypic stands of vegetation that are affected by a plant growth regulator.
