Summary

Beginning in 2006, point infection control operations and aerial distribution of oral rabies vaccines along the US border were performed in Quebec, Canada, to control the potential spread of raccoon rabies. A benefit-cost analysis assessed the economic efficiency of this rabies control programme into the future. In this study, a mathematical simulation model was used to determine the potential spread of raccoon rabies from the 2006 index case, and incidence rates of human post-exposure prophylaxis (PEP), animal testing and human exposure investigations were calculated. Benefits were calculated as the potential savings from reduced numbers of human PEP, animal testing and human exposure investigations owing to control, which ranged from \$47 million to \$53 million. Programme cost scenarios were based on projections of total expenditures, which ranged from \$33 million to \$49 million. Economic efficiency was indicated for approximately half of the modelled scenarios, with the greatest benefit-cost ratios resulting from reduced future programme costs.

Introduction

Rabies is an acute, viral, encephalitic disease unique to mammals (Niezgoda et al., 2002). Following the onset of symptoms, its neurological effects are usually fatal. In North America, wildlife (e.g. raccoons, bats, skunks, foxes) serves as the main reservoir for the disease, including multiple variants where virus transmission is primarily between members of the same species (Blanton et al., 2009). The spread of rabies can have serious impacts to animal and human health, as well as significant costs to the human health system, particularly when exposure occurs in densely populated areas. Rabies prevention is a model for 'One Health' medicine in that wildlife managers, veterinarians and medical doctors collaborate to successfully provide rabies vaccination to wildlife, companion animals, livestock and humans, as well as

public education. This unique collaboration among a myriad of public health professionals provides a blueprint for the eventual successful elimination of a zoonotic disease (Shwiff et al., 2008).

Currently, the raccoon rabies virus variant (hereafter raccoon rabies) is enzootic in much of the Eastern United States, and prevention of its northward spread is of concern in Ontario and Quebec provinces, Canada, (MacInnes et al., 2001; Blanton et al., 2009). A variety of methods are used to manage raccoon rabies at the landscape and population level including: oral rabies vaccination (ORV), trap-vaccinate-release and population reduction. In an economic sense, all of these methods are designed to reduce the monetary damage caused by the presence of the disease and the potential to infect humans, livestock, companion animals and other wildlife species.

The major economic impacts of raccoon rabies are derived from human post-exposure prophylaxis (PEP), animal rabies tests (AT), human exposure investigations (INVT), livestock deaths, pet vaccinations and public education efforts (Meltzer and Rupprecht, 1998a,b; Sterner and Sun, 2004). Recent economic assessments have shown that these economic impacts spike during rabies epizootics, and have attempted to quantify both rabies- and ORV-incurred costs (Uhaa et al., 1992; Kreindel et al., 1998; Chang et al., 2002; Foroutan et al., 2002; Nunan et al., 2002; Shwiff et al., 2007, 2009, 2011). Additional economic analyses have evaluated ORV programmes using benefit-cost analysis (BCA), with increased PEP, AT and pet vaccinations as the principle driver of cost (Meltzer, 1996; Kemere et al., 2002; Shwiff et al., 2008).

Raccoon rabies was first detected in southern Quebec along the US (Vermont) border in 2006. Previously, the province had been considered raccoon rabies free and it is assumed that the disease was introduced via wildlife movement across the international boundary. The number of detected raccoon rabies-positive animal cases increased from four in 2006 to 66 in 2007 and 32 in 2008. Because of the close proximity of human and raccoon populations in Quebec, the wide range (including urban) and density of raccoon populations and continued priority given to raccoon rabies control within the United States, the Quebec government initiated a raccoon rabies control programme. Between 2006 and 2009, several million rabies vaccines targeting raccoons were distributed by air or ground over a 9500 square kilometre area of southern Quebec province to control this outbreak. This raccoon rabies control programme slowed the spread of the disease on the east side of the Richelieu River, 40 km southeast of Montreal city. Only two new cases of raccoon rabies in skunks were detected in the southern part of the infected area in 2009. Quebec effectively halted the spread and reduced the size of the epizootic through the province, thereby neutralizing the potential economic impacts associated with the spread of the disease.

This study provides an innovative bioeconomic methodology to estimate the benefits and costs associated with the Quebec raccoon rabies control programme starting in 2006 and projected until 2018. To estimate the potential benefits of the control programme, the methodology combines a dynamic spatial disease spread model for the simulation of the rabies epizootic among the raccoon population and economic quantification of the associated PEP, AT and INVT frequencies (Rees et al., 2009).

Materials and Methods

Benefit-cost analysis is a common tool used by economists to evaluate, among many others, government

programmes and to determine the efficiency of management efforts. In a BCA, the monetary benefits and costs of programme actions are identified and compared (Nas, 1996). Estimating the economic benefit of preventing the spread of a previously undocumented variant of rabies into the province of Quebec, and potentially the rest of Canada, requires the quantification of non-marketed goods and services. One accepted methodology to value non-market services is the damage-avoided method, which uses the value of resources protected as a measure of the benefits provided by the raccoon rabies control programme. Here, it was posited that the raccoon rabies control programme slowed the movement of raccoon rabies into the study area. The benefits of the control programme were calculated as the savings from reducing the number of PEP, AT and INVT necessary, plus the associated costs that would potentially be borne by individuals as a result of human rabies exposure (e.g. expenditures on over-the-counter medications, lost work time and travel to receive treatment). These avoided costs make up the majority of benefits derived from rabies control programmes (Shwiff et al., 2008, 2009, 2011).

The raccoon rabies control programme began in 2006 and costs included salaries, vaccines, baits, aircraft operations, enhanced surveillance and public communication costs. Actual costs were used from 2006 to 2009 and then extrapolated into the future (up to 2018) based on 2009 levels, as this was the first year of full programme funding. Thus, for this study, total benefits and total costs of the raccoon rabies control programme were estimated from 2007 to 2018. The 12-year study period ending in 2018 used to evaluate the programme was based on practical considerations associated with government agencies ability to project the scale and scope of rabies control activities into the future.

Disease spread modelling

Because benefits are derived from the human population at risk (HPR), the objective of the disease spread simulation in a resident raccoon population was to calculate HPR located in and close to the areas infected by rabid raccoons. The model used was the Ontario Rabies Model (ORM; Rees et al., 2009). The ORM has been validated using genetic data (Rees, 2008; Rees et al., 2008a). Additional information on the ORM behaviour, including sensitivity analysis, is provided in Rees et al. (2008b).

The ORM is an individual-based stochastic and dynamic model using raccoons as simulated objects and has the ability to model the dispersion of raccoon rabies in a raccoon population through time and space. The study region was 32 400 km² and was located in southern Quebec province, delineated to the south by the border

with the United States, to the North by the Saint Lawrence River and the southwest edge of the city of Quebec.

The first raccoon rabies case detected on 6 June 2006 by the passive public health surveillance system in Quebec was used as the index case of two simulated epizootic scenarios; one with control and one without control measures, spanning from 2006 to 2018. The simulated rabies control programmes were located in areas corresponding to the actual vaccination area (2006–2008). The control measures were only an approximation of the real control measures undertaken. For example, population reduction implemented in 2006 and 2007 was not taken into account, and the size of the ORV zone was not adjusted in relation to the geographic spread of raccoon rabies overtime. Hence, these simulations should not be interpreted as an evaluation of the field control programme. No cost reductions in the control programme were specifically simulated; however, the economic analysis incorporated certain efficiency gains associated with future projected baiting scenarios. Tinline, 2007 describes the selection procedure for the representative dispersion area to calculate the HPR, which was calculated using the 2006 population census data (Ludwig et al., 2009a). The HPR calculation follows the criteria proposed by the Institut national de santé publique du Québec (Lambert et al., 2007). The front of the simulated epizootic without control measures (baseline) reached the fringe of the defined study area as soon as 2011, while the simulated epizootics including control measures will not reach the border of the study area in 2018. To extend the baseline population at risk to 2018, the HPR for the epizootic without control measure was extrapolated from 2012 to 2018 based on the 2011 level. Therefore, no population increases or decreases are built into the model for the future (2012–2018) period in the specific case without control measures. Because raccoon rabies spreading North meant that rabies would impact the urban area of Montreal, it was realistic to assume this would be considered a risk for many years into the future by the responsible rabies management and public health agencies. The difference between the baseline HPR without control and the estimated HPR with control was those individuals that were not at risk of raccoon rabies exposure because of the control programme (Fig. 1). This difference between the two simulations represents the number of individuals protected by the programme and was used to calculate the benefits of the raccoon rabies control programme.

Derivation of benefits

The number of individuals protected or ‘saved’ by the programme was then combined with the rates of incidence of PEP, AT and INVT per 100 000 people to

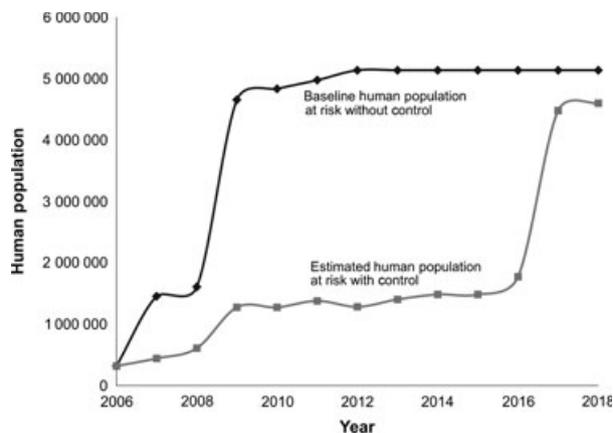

Fig. 1. Annual human population estimated to be at risk for rabies exposure (2006–2018).

monetize the benefits of the programme. To accomplish this, the annual case frequency of PEP and AT during raccoon rabies epizootics in the Eastern United States and Eastern Canada was used as proxies (Shwiff et al., 2008). Data regarding annual PEP and AT rates reported in New Jersey (Uhaa et al., 1992), New York (Wyatt et al., 1999) and New Brunswick (Department of Health, New Brunswick Provincial Government 2008, unpublished data) were used to determine the hypothetical case frequency that could have existed in the absence of a raccoon rabies control programme. New Jersey, New York and New Brunswick raccoon rabies epizootic PEP rates were reported as 66, 43.5 and 14; AT rates were reported as 483, 65 and 45 per 100 000 people, respectively. Determination of the number of INVT was accomplished using data provided by the Direction de santé publique de l'Agence de la santé et des services sociaux de la Montérégie. Data collected in Montérégie, Quebec, from 1995 to 2006 (excluding bat exposure) indicate that for every PEP administered an average 8.71 (range, 4.07–20.17) INVT occurred. Therefore, in this report, the number of INVT was directly estimated based upon the PEP savings.

The annual total benefits equal PEP, AT and INVT costs owing to raccoon rabies cases saved. The predicted frequency level of PEPs per 100 000 saved was the average number of PEPs per 100 000 minus the actual number (the average number of PEPs from 1995 to 2006 reported in the study area). PEPs previous to 2006 raccoon variant rabies epizootic were the result of contact with different species of animals (excluding bat exposures). This information was combined with the costs associated with PEP annually. Two different levels of PEP costs were used for the analysis. For level 1, no indirect costs were included, and for level 2, the cost of PEP was increased by 33% to

include indirect costs associated with rabies exposure. Shwiff et al. (2007) provides the most current and detailed estimation of direct and indirect costs associated with a rabid animal exposure. Direct costs refer to the vaccine, other biological materials and the health professional salaries, while indirect costs refer to over-the-counter medicines, travel to physicians and lost time from work associated with human rabies exposure. Indirect costs composed approximately one-third (33%) of the total costs associated with a rabid animal exposure. The calculation of the cost savings related to AT was similar. The predicted frequency level of AT was compared to the actual number of ATs (the average number from 1995 to 2006 reported in the study area). This information was combined with the human population saved and the costs associated with AT, to calculate the cost savings during a particular year. The number of INVT was derived from the number of PEPs. This information was combined with the costs associated with INVT, to calculate the cost savings during a particular year.

The monetary savings per PEP, AT and INVT avoided were determined given the calculated number of cases prevented multiplied by the cost. The cost information for PEP, AT and INVT was estimated at \$1463.75 (rabies vaccines: \$860 for five doses, immunoglobulin: \$516 for a mean of 8 ml, salary of a nurse: \$45/h, mean duration of PEP administration: 1.5 h. Costs and duration were provided by the Ministère de la santé et des services sociaux du Québec), \$269 (sample collection: \$172, sample shipping: \$5, travel: \$40.60, laboratory processing: \$30, quarantine of domestic animals: \$20, indemnification payment: \$2.30). Costs were provided by Canadian Food Inspection Agency) and \$124 (mean salary of a health professional: \$55/h, mean duration of an investigation: 2.25 h. Costs and duration were provided by the Ministère de la santé et des services sociaux du Québec) in 2008 Canadian dollars (CAD) per incident, respectively.

Estimation of these cost saving components permits the determination of the total programme benefits. The calculation of benefits was over the entire time period since the initiation of the control programme. All estimates of cost savings were calculated in 2008 dollars. Therefore, the total benefits calculated represent the present value of the entire raccoon rabies control programme for each year, from 2006 to 2018. It should be noted that not all benefits created by controlling raccoon rabies could be captured in this analysis. For example, the savings associated with a reduction in companion animal and livestock vaccinations along with any treatment (e.g. emergency care, quarantine, medications) were not factored into the analysis because of data limitations. Omission of these benefits creates more conservative programme benefit-cost ratios (Kemere et al., 2002).

Derivation of costs

Three control programme cost scenarios were developed to model future costs (Table 1). Scenario 1 does not include any future cost reductions; however, in Scenarios 2 and 3, the potential for future efficiency gains in the raccoon rabies control programme was modelled as reductions in future costs. For example, future efficiency gains could be produced by new ORV baits with higher efficacy potentially reducing the number of baits distributed on the landscape leading to an overall reduction in costs. The parameter values of the disease spread model were not modified to reflect possible impact of the choice of any of the three cost scenarios. This analysis determined the overall impact of reduced budgetary expenditures on the breakeven year and on programme efficiency. Contingency actions costs or costs associated with a disruption (e.g. flare-up of rabies in a previously controlled area) in the control programme were not included in this analysis. Contingency actions are not always necessary for programme success, and future analysis could include an examination of the impact of contingency actions.

Results

Total benefits accruing to the raccoon rabies control programme were the calculated savings owing to the programme (the projected prevented number of PEPs, ATs and INVTs and their cost to society) over the study period 2007–2018 (Tables 2 and 3). When the estimated benefits were compared to the costs of the raccoon rabies control programme, the potential ratios of benefits to

*All numbers in 2008 CAD.

costs were determined. In this analysis, total (cumulative) programmatic benefit-cost ratios ranged from 0.96 to 1.55 (Tables 4 and 5). This indicates every dollar spent on the raccoon rabies control programme saves between \$.96 and \$1.55 in prevented costs to society.

Level 1

This level of benefits omitted any savings derived from indirect costs associated with PEP (Table 2). Future reductions in programme costs matter in terms of overall programme economic efficiency. Under scenario 1, the overall programme benefits are approximately equal to costs with a ratio of benefits to costs of .98, mainly owing to the static nature of long-term programme costs. For scenarios 2 and 3, overall benefits exceed the costs when estimated over the life of the programme.

Level 2

Inclusion of the indirect cost savings associated with PEP more accurately reflects the cost burden associated with human exposure to rabies (Table 3). Under all costs scenarios, overall programme benefits exceed costs. The combination of indirect costs associated with PEP and long-term programme cost savings provides the best potential returns associated with the programme, with benefits (\$6 044 668) approximately four times greater than costs (\$1 533 200).

Discussion

Successful elimination of the spread of an expensive and deadly disease like raccoon variant rabies often leaves economists, public health organizations and legislators

Table 5. Estimated benefit-cost ratios for level 2 benefits (post-exposure prophylaxis indirect cost savings included) and three calculated cost scenarios (costs maintained versus future efficiency gains), from 2007 to 2018

Year	Scenario 1		Scenario 2		Scenario 3	
	BCR	BCR/year	BCR	BCR/year	BCR	BCR/year
2007	0.03	0.37	0.04	0.37	0.05	0.37
2008	0.07	0.37	0.09	0.37	0.10	0.37
2009	0.18	1.45	0.24	1.45	0.27	1.45
2010	0.30	1.53	0.40	1.53	0.44	1.53
2011	0.43	1.55	0.56	1.55	0.62	2.58
2012	0.56	1.66	0.73	1.66	0.81	2.76
2013	0.68	1.61	0.89	3.21	1.00	2.68
2014	0.81	1.57	1.06	3.14	1.18	2.62
2015	0.93	1.57	1.22	3.14	1.36	3.93
2016	1.04	1.45	1.37	2.89	1.52	3.62
2017	1.07	0.28	1.40	0.56	1.56	0.71
2018	1.08	0.23	1.42	0.46	1.58	0.58

wondering what would have been the monetary consequences if the programme had not been successful. This study provided a methodology to estimate the economic impact of limiting the spread of rabies, when compared with classically used methods. One main difficulty in bioeconomic modelling of most zoonotic diseases lies in the accurate prediction of HPR. Previously reported methodologies for the calculation of the HPR for rabies either consider the entire study area at risk once the first case has been detected (Uhaa et al., 1992; Aubert, 1999) or consider that only a restricted part of the study area is at risk at the detection of the first case and then expand through the area based on arbitrary choices (Shwiff et al., 2009) or according to the expansion of the epizootic front

at constant speed (Kemere et al., 2002; Shwiff et al., 2008). The most significant contribution of this study includes adding additional sophistication to the economic analysis by enhancing the quantification of HPR based upon the simulation of disease spread within the raccoon population. The use of this mathematical model made it possible to include many biological aspects neglected by more conventional approaches (i.e. biology of the disease vector, such as birth rate, mortality rates, movements) and produce estimates of disease spread more specific to the conditions in the study area. This study shows preventing the entry of the disease into a highly populated urban area such as Montreal is crucial to achieve cost efficiency in a rabies control programme and should be prioritized as an objective of the programme. For these reasons, we believe this study illustrates a useful tool for decision-making.

Another challenge of this study was determining the hypothetical annual frequencies of public health interventions (PEP, AT and INVT) that would have existed in the absence of a raccoon rabies control programme, which were used to calculate damages avoided in the economic analysis. The estimated frequencies were based on information from the raccoon rabies epizootics in New Brunswick, New Jersey and New York. The use of these average and adjusted frequencies reduces uncertainty of the monetary value of damages avoided; however, inclusion of additional information would further refine the results, thus underlining the need for more reported and published data on the effects of rabies epizootics on public health interventions. A range of potential programme benefits (levels 1 and 2) were estimated to compare with three programmatic control cost scenarios. This prospective analysis of the control programme to prevent the spread and eventual elimination of the emerging raccoon rabies in the province of Quebec indicated economic efficiency of the programme for a variety of modelled outcomes. Some modelled outcomes indicated that efficiency is not possible given the derived benefits and the estimated costs signalling a potentially inefficient use of government expenditures.

This analysis estimated a range of potential future control programme costs. A static budget into the future, while potentially realistic, does not convey the possibility of reduced control programme expenditures owing to either efficiency gains within the programme or containment or elimination of the raccoon rabies variant in the province. For example, in Texas, an initial ORV programme contained the spread of the domestic dog coyote-variant rabies and an ORV zone was established at the United States – Mexico border to prevent the reintroduction into Texas (Sidwa et al., 2005). Costs associated with containing the spread of the variant in Texas were higher than the subsequent years when costs were only

related to maintaining the ORV zone (Shwiff et al., 2008). It is possible that similar efficiency gains through economies of scale in the baiting programme or potential increases in vaccine efficiency could also be realized with the control programme. Following the completion of the study, the inclusion of future programme efficiency gains with the BCA has been supported. In Quebec, despite the diminishing budget for rabies control and the size of the baited area remaining consistent, the efficiency of baiting techniques has been ameliorated.

In conclusion, economic efficiency is one of the many factors that play a role in determining the utility of rabies control programmes. This study provides an example of how to estimate the cost efficiency of a raccoon rabies control programme, even though many unknowns were involved in the original decision. In this work, stochastic elements were only included to simulate disease spread. This analysis can be used as the foundation for several future analyses; first, the incorporation of stochasticity into the economic parameterizing of elements such as PEP, AT and INVT, and second, the use of economic computer simulation software to model the change in economic activity as a result of the control of raccoon rabies. All bioeconomic modelling systems possess an inherent variability, and the inclusion of a more comprehensive set of stochastic components in the modelling process would provide for probability distributions of the bioeconomic outputs from the model instead of a limited, discrete set of scenario results (Ludwig et al., 2009b). Future research to model the economic impact of government spending to prevent the spread of raccoon rabies in Quebec could use the information provided in this analysis to inform economic impact input–output modelling software. This would certainly be of even greater interest for decision-makers and stakeholders in the process of programme implementation or continuity evaluation.
