EFFECTS OF MANAGEMENT PRACTICES ON GRASSLAND BIRDS:
HORNED LARK

Grasslands Ecosystem Initiative
Northern Prairie Wildlife Research Center
U.S. Geological Survey
Jamestown, North Dakota 58401
This report is one in a series of literature syntheses on North American grassland birds. The need for these reports was identified by the Prairie Pothole Joint Venture (PPJV), a part of the North American Waterfowl Management Plan. The PPJV recently adopted a new goal, to stabilize or increase populations of declining grassland- and wetland-associated wildlife species in the Prairie Pothole Region. To further that objective, it is essential to understand the habitat needs of birds other than waterfowl, and how management practices affect their habitats. The focus of these reports is on management of breeding habitat, particularly in the northern Great Plains.

Suggested citation:

Species for which syntheses are available or are in preparation:

- American Bittern
- Mountain Plover
- Marbled Godwit
- Long-billed Curlew
- Willet
- Wilson’s Phalarope
- Upland Sandpiper
- Greater Prairie-Chicken
- Lesser Prairie-Chicken
- Northern Harrier
- Swainson’s Hawk
- Ferruginous Hawk
- Short-eared Owl
- Burrowing Owl
- Horned Lark
- Sedge Wren
- Loggerhead Shrike
- Sprague’s Pipit
- Grasshopper Sparrow
- Baird’s Sparrow
- Henslow’s Sparrow
- Le Conte’s Sparrow
- Nelson’s Sharp-tailed Sparrow
- Vesper Sparrow
- Savannah Sparrow
- Lark Sparrow
- Field Sparrow
- Clay-colored Sparrow
- Chestnut-collared Longspur
- McCown’s Longspur
- Dickcissel
- Lark Bunting
- Bobolink
- Eastern Meadowlark
- Western Meadowlark
- Brown-headed Cowbird
EFFECTS OF MANAGEMENT PRACTICES ON GRASSLAND BIRDS:

HORNED LARK

January 2000
(revised January 2002)
Information on the habitat requirements and effects of habitat management on grassland birds were summarized from information in more than 4,000 published and unpublished papers. A range map is provided to indicate the relative densities of the species in North America, based on Breeding Bird Survey (BBS) data. Although birds frequently are observed outside the breeding range indicated, the maps are intended to show areas where managers might concentrate their attention. It may be ineffectual to manage habitat at a site for a species that rarely occurs in an area. The species account begins with a brief capsule statement, which provides the fundamental components or keys to management for the species. A section on breeding range outlines the current breeding distribution of the species in North America, including areas that could not be mapped using BBS data. The suitable habitat section describes the breeding habitat and occasionally microhabitat characteristics of the species, especially those habitats that occur in the Great Plains. Details on habitat and microhabitat requirements often provide clues to how a species will respond to a particular management practice. A table near the end of the account complements the section on suitable habitat, and lists the specific habitat characteristics for the species by individual studies. A special section on prey habitat is included for those predatory species that have more specific prey requirements. The area requirements section provides details on territory and home range sizes, minimum area requirements, and the effects of patch size, edges, and other landscape and habitat features on abundance and productivity. It may be futile to manage a small block of suitable habitat for a species that has minimum area requirements that are larger than the area being managed. The Brown-headed Cowbird (Molothrus ater) is an obligate brood parasite of many grassland birds. The section on cowbird brood parasitism summarizes rates of cowbird parasitism, host responses to parasitism, and factors that influence parasitism, such as nest concealment and host density. The impact of management depends, in part, upon a species’ nesting phenology and biology. The section on breeding-season phenology and site fidelity includes details on spring arrival and fall departure for migratory populations in the Great Plains, peak breeding periods, the tendency to renest after nest failure or success, and the propensity to return to a previous breeding site. The duration and timing of breeding varies among regions and years. Species’ response to management summarizes the current knowledge and major findings in the literature on the effects of different management practices on the species. The section on management recommendations complements the previous section and summarizes specific recommendations for habitat management provided in the literature. If management recommendations differ in different portions of the species’ breeding range, recommendations are given separately by region. The literature cited contains references to published and unpublished literature on the management effects and habitat requirements of the species. This section is not meant to be a complete bibliography; a searchable, annotated bibliography of published and unpublished papers dealing with habitat needs of grassland birds and their responses to habitat management is posted at the Web site mentioned below.

HORNED LARK
(Eremophila alpestris)

Key to management is maintaining areas with short, sparse vegetation by burning, mowing, or grazing.

Breeding range:
There are 21 subspecies of Horned Lark (Beason 1995). Subspecies associated with the Great Plains include E. a. enthymia, E. a. leucolaema, and E. a. praticola. Horned Larks are year-round residents from southern British Columbia to southern Manitoba, south along the west coast of the United States to Mexico, and east to the east coast. Migratory populations of Horned Larks exist from northern British Columbia and Alaska, east to northern and eastern Quebec and Newfoundland, and also in southern Ontario and northern Michigan, Minnesota, and Wisconsin (National Geographic Society 1999). (See figure for the relative densities of the species in the United States and southern Canada, based on Breeding Bird Survey data.)

Suitable habitat:
Horned Larks prefer areas with short, sparse herbaceous vegetation with little or no woody vegetation (Beason 1970; Wiens 1973; Creighton 1974; Skinner 1974, 1975; Rotenberry and Wiens 1980; Dale 1983; Renken 1983; Sample 1989; Camp and Best 1993; Prescott and
Preferred habitats include cropland, herbaceous fencerows, road rights-of-way, pasture, recently cut hayland, and shrubsteppe (Bent 1942; Cassel 1952; Graber and Graber 1963; Speirs and Orenstein 1967; Beason 1970; Strong 1971; Porter and Ryder 1974; Stewart 1975; Ducey and Miller 1980; Ryder 1980; Kantrud 1981; Best and Hill 1983; Faanes 1983; Gremaud 1983; Castrale 1985; Kahl et al. 1985; Greer 1988; Best et al. 1990; Bryan and Best 1991; Camp and Best 1993; Johnson and Schwartz 1993a; Hartley 1994a,b; Patterson 1994; Anstey et al. 1995; Faanes and Lingle 1995; Kerley and Anderson 1995; King and Savidge 1995; Kent and Dinsmore 1996; Patterson and Best 1996; Best et al. 1997; Davis et al. 1997; McMastor 1998; McMastor and Davis 1998; Martin and Forsyth 2003). Occupied areas are characterized by moderate coverage (10-37%) of bare ground (Speirs and Orenstein 1967, Skinner 1974, Dale 1983, Greer 1988, Sample 1989, Davis and Duncan 1999). Horned Larks may be present in newly seeded dense nesting cover (DNC) (Prescott and Murphy 1999), but relatively few if any Horned Larks were observed in established Conservation Reserve Program lands (CRP), Permanent Cover Program (PCP) lands, or DNC (Renken and Dinsmore 1987; Dale 1992, 1993; Johnson and Schwartz 1993a,b; Hartley 1994a,b; Johnson and Igl 1995; Patterson and Best 1996; Best et al. 1997). PCP was a Canadian program that paid farmers to seed highly erodible land to perennial cover; it differed from CRP in that haying and grazing were allowed annually in PCP.

In Colorado, Kansas, Montana, Nebraska, Oklahoma, Texas, and Wyoming, Horned Lark abundance was negatively correlated with percent forb cover, maximum vegetation height, and height of emergent forb and shrub cover (Rotenberry and Wiens 1980). In northcentral Colorado, mean vegetation measurements for occupied areas were 65% cover of short grasses (e.g., blue grama [Bouteloua gracilis] and buffalo grass [Buchloe dactyloides]), 2% cover of mid-grasses (e.g., slimspike three-awn [Aristida longiseta], western wheatgrass [Pascopyrum smithii]), little bluestem [Schizachyrium scoparium]), 6% sedge (Carex spp.) cover, 7% forb cover, 2% cactus cover, 0.8% shrub cover, 17% bare ground, 1% rock cover, and 7.2 cm mean vegetation height (Creighton 1974). In another Colorado study, Bock et al. (1999) compared the abundance of Horned Larks between upland (mixed-grass prairie) and lowland (tallgrass prairie or tame hayland) grassland plots. Horned Larks were significantly more abundant on upland than on lowland plots. In mixed-grass pastures in North Dakota, Horned Lark density was higher in pastures with <10% cover of western snowberry (Symphoricarpos occidentalis) and silverberry (Elaeagnus commutata) than in pastures with 30-80% cover of these shrubs (Arnold and Higgins 1986). The highest densities of Horned Larks occurred on transects with the lowest height and density of vegetation, regardless of the presence or absence of shrubs. Horned Larks in Saskatchewan occupied areas having little or no vegetation or litter (Dale 1983, Davis and Duncan 1999). Based on vegetation at nest sites in Saskatchewan, Horned Lark occurrence was positively associated with number of contacts of narrow-leaved (<5 mm wide) grasses <10 cm high and was negatively associated with vegetation height (SWCC 1997). In Alberta, the species preferred short grass that was uniform in height (Prescott and Murphy 1996).

Breeding habitat in Missouri cropland consisted of shallow (<0.4 cm), sparse (<25%) litter cover, short (<10 cm) vegetation, and no woody stems (Kahl et al. 1985). Skinner (1974) found that Horned Larks in Missouri used areas of bare ground caused by cattle and American bison (Bison bison) disturbances. In Illinois, pasture and alfalfa (Medicago sativa) hayland were used only in early spring (prior to 5 May), when vegetation was short and sparse (Gremaud 1983). In Illinois cropland, territory density was highest in hay stubble or corn stubble fields than in plowed fields (Beason and Franks 1974). Beason (1970) found territories were densest in
discarded cropland and recently cut hayfields (with vegetation heights of about 10 cm). Nests in
cropland and hayland were placed on the ground in depressions, usually on the leeward side of a
protective tuft of grass, rock, or other object in a barren area. Nests in Colorado often were
found near cowpies (Porter and Ryder 1974, Ryder 1980, With and Webb 1993). Nests in North
Dakota occurred in shallow depressions on bare or sparsely vegetated ground (Stewart 1975). In
Iowa, the use of rowcrop fields significantly increased as their proximity to woody habitats
decreased (Gremaud 1983). Horned Larks were common in strip-intercropped fields (i.e.,
planting rowcrops, legumes, and small grains in a series of adjacent, narrow strips) in Iowa
(Stallman and Best 1996). In Nebraska, Horned Larks were absent from areas of extensive corn
production, possibly because the timing of crop planting disrupted nesting activity (Faanes and
Lingle 1995). Horned Larks in Indiana preferred conventionally tilled (fields tilled in the spring
prior to planting) fields over no-tillage fields (fields untilled between harvest and planting with
seed planted directly into crop residue) (Castrale 1985). In Alberta, short vegetation appeared to
be a factor in early-season preference for cropland (Martin and Forsyth 2003). Short vegetation
also was associated with higher numbers of productive territories and higher productivity when
compared to areas of taller vegetation. Breeding territories were observed in both spring- and
winter-wheat fields regardless of whether conventional or conservation tillage was used.
Conventional tillage was defined as multiple cultivations prior to planting; conservation tillage
was defined as planting directly into the previous year’s stubble. A table near the end of the
account lists the specific habitat characteristics for Horned Larks by study.

Area requirements:
In Colorado, Horned Lark territories in lightly grazed shortgrass pastures ranged from 0.3
to 1.5 ha and averaged 0.7 ha (Boyd 1976). Territories in heavily summer- and winter-grazed
shortgrass pastures in Colorado ranged from 1.0 to 1.7 ha and averaged 1.5 ha (Wiens 1970,
1971). Territories in mixed-grass pasture and idle mixed-grass averaged 1.1 ha and 1.6 ha,
respectively (Wiens 1971). In midwestern cropland, territory sizes ranged from 0.6 to 3.1 ha
with an average of 1.6 ha (Beason and Franks 1974). Territory sizes in disced cropland and tame
hayland ranged in size from 1.0 to 2.5 ha (Beason 1970). Bent (1942) reported a Horned Lark
territory in Illinois that was only 81 m² (0.008 ha). In tallgrass prairie fragments in Illinois,
Horned Larks were found in patches <10 ha (Herkert 1991).

No studies have investigated a relationship between patch size and nest success or patch
size and rates of brood parasitism by Brown-headed Cowbirds (*Molothrus ater*). Bock et al.
(1999) compared the abundance of Horned Larks between interior and edge locations. Edge was
defined as the interface between suburban development and upland or lowland habitat, and
interior locations were 200 m from edge. Horned Larks occurred more frequently on interior
plots than on edge plots but the difference was not significant due to high variation in numbers
of Horned Larks among plots.

**Brown-headed Cowbird brood parasitism:**
The Horned Lark is an infrequent victim of the Brown-headed Cowbird (Friedmann
1963, Friedmann et al. 1977). Parasitism rates vary from 0% of 163 nests (Maher 1973) to 60% of
84 nests (Koford et al. 2000). Refer to Table 1 in Shaffer et al. (2003) for rates of cowbird
brood parasitism. Horned Larks may be multiply-parasitized (Peabody 1899, Robbins 1949,
Friedmann 1963, SWCC 1997, Koford et al. 2000). In Kansas and North Dakota, parasitism in
initial clutches may have been less than in subsequent clutches because first clutches were laid
before the onset of the breeding season of Brown-headed Cowbirds (Hill 1976, Koford et al. 2000). In North Dakota, no early nests (discovered prior to 15 May) were parasitized, but 50 of 84 (60%) nests found after 15 May were parasitized (Koford et al. 2000). No parasitism was observed in eight initial clutches laid from mid-March to mid-April in western Kansas, but 14 of 22 second clutches were parasitized from mid-May to mid-June (Hill 1976). In the Great Plains, the breeding season of the Brown-headed Cowbird generally extends from early May to late July and peaks from late May to mid-July (Stewart 1975, Ortega 1998).

Breeding-season phenology and site fidelity:

Horned Larks may be year-round residents in all but the most northern parts of their breeding range (Beason 1995). Horned Larks begin arriving on their breeding range in large numbers from late February to late March and depart from late October to late November (Maher 1973, Stewart 1975, Salt and Salt 1976, Faanes 1981, Janssen 1987). Peak nesting in North Dakota occurred from late April to late July (Stewart 1975). Dubois (1935) noted two peaks in nesting activity in Montana, one at the end of April and another in early June. Peak nesting activity in Colorado occurred from April to early May (Creighton 1974). The species has exhibited both breeding-site and mate fidelity (George 1952, Ryder 1972, Boyd 1976). In Michigan, six of 12 banded adults returned as breeders the year following banding (George 1952). In Colorado, six of 15 banded adults were recaptured at the banding site the following year (Ryder 1972). Two banded males returned to the same study area the year following banding, but held different territories. In another Colorado study, 23 of 35 females and 23 of 36 males returned the year following banding (Boyd 1976). An additional two males were present on the previous year’s territories in February and March but may have perished in a March snowstorm. Only one of the 23 males did not use the same territory as was used the previous year. Almost one half of the 23 returning females returned to the same mate the year following banding. Six of 136 Horned Larks marked as juveniles returned to breed on the study area. Also in Colorado, a male Horned Lark was resighted six years later in the same general area in which he was banded (Clapp et al. 1983).

Horned Larks raise up to three broods per season (Peabody 1899; George 1952; Maher 1973, 1974; Porter and Ryder 1974; Boyd 1976; Salt and Salt 1976). In Saskatchewan, the average number of clutches produced per female was estimated at two or three; some individuals produced up to five clutches (Maher 1973). Renesting is common after the failure of an initial nesting attempt (George 1952, Maher 1973).

Species response to management:

Horned Larks were present in South Dakota mixed-grass areas 1 mo postburn but were absent from unburned areas (Huber and Steuter 1984). In native rough fescue (Festuca scabrella) grasslands in Saskatchewan, breeding Horned Larks were present in low numbers (ranging from 0.02 to 0.06 birds/ha) in both a fall-burned plot and an unburned plot (Pylypec 1991). In Saskatchewan mixed-grass prairie that was burned in late summer, peak densities of Horned Larks were recorded 2 yr postburn (Maher 1973). In Wyoming, Kerley and Anderson (1995) observed Horned Larks in burned shrubsteppe. In North Dakota, Horned Larks avoided a mixed-grass hayland that had been mowed during the previous year (Kantrud 1981). Horned Larks were not present in Colorado hayland, which had been flood-irrigated during spring and early summer, mowed during July, and occasionally grazed by cattle during fall and winter (Bock et al. 1995, Bock et al. 1999).
Illinois, Horned Larks were present in hayland composed of a mixture of native and tame vegetation (Graber and Graber 1963). Horned Larks in another Illinois study were common in a tame hayfield (vegetation height was <10 cm) early (March through May) in the breeding season, but abandoned the hayfield by early June, presumably due to the growth of vegetation (Beason 1970). Horned Larks became abundant in the hayfield after it was cut (vegetation height after cutting was 10-15 cm) in mid-June, although it appeared that no territories were established. By early July, vegetation in the hayfield had grown to 40 cm tall and the birds abandoned the field. Horned Larks occurred in tame hayland in Minnesota and Wisconsin (Faanes 1981). In Saskatchewan, Horned Larks were common in hayland that was mowed once annually in July; surveys were conducted just prior to mowing (Dale et al. 1997).

In shortgrass pastures in Colorado, Horned Larks preferred heavily grazed over lightly or moderately grazed pastures (Giezentinanner and Ryder 1969; Ryder and Cobb 1969; Giezentinanner 1970a, b; Ryder 1980). Wiens (1970) found that Horned Larks in Colorado preferred heavily winter-grazed sites over heavily summer-grazed sites for breeding. In North Dakota mixed-grass prairie, Horned Larks were found on twice-over rotation pastures, short-duration pastures, and season-long grazing pastures (Messmer 1990). Short-duration grazing involved a system of pastures rotated through a grazing schedule of about 1 wk grazed and 1 mo ungrazed, repeated throughout the season. Twice-over rotation involved grazing a number of pastures twice per season, with about a 2-mo rest in between grazing. Horned Larks preferred silty range sites that were characterized by loamy soils, 1-15% slope, mean grass coverage ranging from 17 to 65%, low shrub cover, and moderate to high litter cover; maximum vegetation height ranged from 50 to 70 cm and average litter depth ranged from 3.8 to 9.1 cm. Horned Larks also were present in shallow-to-gravel sites that were characterized by shallow, coarse-textured soil, sparse cover, and reduced litter. In North Dakota, areas mowed or grazed by sheep had fewer shrubs than areas not mowed or grazed; Horned Larks preferred these areas because of reduced shrub density (Higgins 1986). In Missouri, Horned Larks were most common in heavily grazed native or tame pastures, followed by moderately grazed pastures; they were absent from idle grasslands and haylands (Skinner 1974, 1975; Skinner et al. 1984). Vegetation that was >30 cm tall was avoided. In Saskatchewan, nests were observed in moderately to heavily grazed shortgrass (Strong 1971). Anstey et al. (1995) in Saskatchewan and Prescott (1997) in Alberta found that Horned Larks preferred mixed-grass pastures over tame pastures. No preference, however, was exhibited between mixed-grass pastures and tame pastures in other studies from Alberta and Saskatchewan (Prescott and Wagner 1996, Davis et al. 1997, Sutter and Brigham 1998, Davis and Duncan 1999).

Horned Larks are more common in cropland than in CRP (Johnson and Schwartz 1993a, Patterson 1994, Johnson and Igl 1995). Horned Larks were not observed in CRP in Indiana, Iowa, Kansas, Michigan, Missouri, and Nebraska (Patterson 1994, Best et al. 1997). Horned Larks in Minnesota, Montana, North Dakota, and South Dakota were most frequently observed in CRP that had been planted to native grasses (Johnson and Schwartz 1993b). They were less frequently observed in CRP fields planted to introduced grasses and legumes, and were absent from wildlife food plots and tree plantings. Horned Larks were absent from tame DNC and idle mixed-grass in North Dakota (Renken and Dinsmore 1987). In Alberta, Horned Larks were present in newly seeded DNC (Prescott and Murphy 1999). In Saskatchewan, Horned Larks were not present in DNC or were present in low numbers compared with low nesting cover (bluegrass [Poa]/fescue [Festuca] mixture) and idle mixed-grass prairie (Dale 1992, 1993; Hartley 1994a, b). Also in Saskatchewan, Horned Larks were more abundant in cropland on
conventional, minimum-tillage, and organic farmland than in DNC (Shutler et al. 2000). Presence of Horned Larks was negatively related to number of wetlands within 2.8 km² of point counts and by area of woody vegetation. Horned Larks were not detected in wetlands or wetland margins. Horned Larks were common in PCP, but occurred significantly more frequently in cropland (McMaster 1998, McMaster and Davis 1998). The frequency of occurrence of Horned Larks in PCP was significantly higher in grazed PCP sites than in hayed PCP sites.

Horned Lark densities in Colorado, Idaho, North Dakota, Utah, and Wyoming were not influenced by use of malathion, carbaryl in oil, and carbaryl bait for grasshopper (Orthoptera) control (George et al. 1995). At the Pawnee National Grassland in Colorado, malathion and toxaphene were applied at rates of 0.6 kg/ha and 1.1 kg/ha, respectively (McEwen and Ells 1975). Densities of Horned Larks were about 1 pair per ha before application of insecticides. Seventeen days after application, numbers of Horned Larks decreased about 30% on toxaphene plots, but remained stable on malathion and untreated plots. Nestlings were killed by toxaphene applications. Mean toxaphene level of 13 Horned Larks collected between 1 and 28 d postspray for analysis of residue was 5.4 parts per million (ppm). At 58 d, two birds had toxaphene residues of 4.6 and 4.1 ppm. At 85 d, two birds had toxaphene residues of 2.3 and 2.9 ppm. Two dead meadowlarks contained toxaphene residues of 4.5 and 2.7 ppm. On malathion plots, only Horned Larks collected through 31 hr postspray contained measurable (≥0.4 ppm) whole-body residues. Four Horned Larks from the untreated area contained 0.5 to 2.0 ppm toxaphene, indicating insecticide drift. No malathion residue was found in two birds from untreated plots. In New Mexico, toxaphene applied at 1.1 kg/ha caused mortality in Horned Larks and a decline in numbers (McEwen et al. 1972). No effects were observed from applications of 448 g/ha carbaryl or 476 g/ha malathion. Horned Larks numbers declined significantly on guthion-treated plots at the 280 g/ha application.

In Montana, numbers of Horned Larks were unaffected by application rates of 175 g/ha of BAY 77488*1 (phenylglyoxylonitrile oxime 0,0-diethyl phosphorothioate) (McEwen et al. 1972). Rates of 322 and 651 g/ha caused significant declines in Horned Lark numbers between pre- and post-spray censuses. Horned Lark numbers declined significantly on areas sprayed with 441 and 672 g/ha applications of fenitrothion. In Wyoming, diazinon applied at 350-560 g/ha caused mortality in Horned Larks and a significant decline in numbers (McEwen et al. 1972). No significant declines in Horned Larks were caused by Mobam* (benzo [b]thien-4-yl methylcarbamate) applied at a rate of 210 g/ha. In Montana and Wyoming, numbers did not decline significantly with 140, 210, or 280 g/ha rates of Baygon* (o-isopropoxyphenyl methylcarbamate) (McEwen et al. 1972). In Wyoming, Horned Lark mortality was observed after fenthion, a chemical used to control mosquitoes (Culicidae), was aerially applied at a rate of 47 g/ha to an irrigated meadow (DeWeese et al. 1983). Applications of chlorpyrifos on wheat fields (applied at rates of 1.0 kg in 18.9 L water/ha and 0.56 kg in 18.9 L water/ha) in Montana resulted in reduced cholinesterase activity in the brains of Horned Larks compared to a control group (McEwen et al. 1986).

Numbers of Horned Larks in Wyoming shrubsteppe were significantly higher in areas that were treated 20-22 yr previous to the study with 2,4-D to remove sagebrush than in untreated (i.e., unburned and not sprayed with herbicides) areas (Kerley and Anderson 1995).

*References to chemical trade names does not imply endorsement of commercial products by the Federal Government.
Untreated areas contained higher shrub density, higher percent shrub cover, and taller shrubs than treated areas. Grazing intensity also was lower on untreated areas. In Ontario corn fields, the mean number of Horned Larks did not differ between pre- and post-applications of the granular insecticides fonofos and terbufos, which are used to control corn rootworm (*Diabrotica* spp.), or between treated fields and control fields (Knapton and Mineau 1995). In areas managed for lowbush blueberries (*Vaccinium angustifolium*) in Maine, Horned Larks were present only in areas recently sprayed with the herbicide hexazinone at a rate of 4 kg/ha (Vickery 1993). Horned Larks preferred the sparse vegetation cover.

Clark and Karr (1979) studied the effects of roads and interstate highways on the density of Horned Larks in central Illinois. They found that the density of Horned Larks increased with distance from the road or highway. In a Saskatchewan study that examined whether the abundance of grassland birds differed between roadsides and trailsides, abundance of Horned Larks was not significantly different along trailsides than along roadsides (Sutter et al. 2000). Roads were defined as traveling surfaces with adjacent drainage ditches planted to smooth brome (*Bromus inermis*) and ending with a fence 11-18 m from the traveling surface. Trails were defined as a single pair of wheel ruts visually indistinct from surrounding habitat in terms of plant structure and composition. Habitat along roads and trails were parcels of lightly to moderately grazed native prairie >256 ha.

**Management recommendations:**

Burn in the spring to reduce woody species (Skinner et al. 1984).

Burning, mowing, or grazing can be used interchangeably to create short, sparse vegetation that Horned Larks prefer (Skinner 1974, 1975; Huber and Steuter 1984; Skinner et al. 1984).

Control shrub growth in mixed-grass pastures in North Dakota by allowing mowing or grazing by sheep (Arnold and Higgins 1986).

In mesic areas, allow moderate grazing to increase habitat patchiness and bird diversity (Skinner 1974, 1975; Ryder 1980; Skinner et al. 1984).

When pest management is required, use only rapidly degrading chemicals of low toxicity to nontarget organisms and apply at the lowest application rates possible (McEwen et al. 1972). Avoid pest outbreaks by maintaining range in good condition. Overgrazed and drought-affected areas tend to be more prone to insect outbreaks.

Reduce amount of grassland edge near suburban interfaces (Bock et al. 1999).

Road construction plans should consider the effects of roads on bird densities in rights-of-way and ≤500 m from rights-of-way (Clark and Karr 1979).

* In an effort to standardize terminology among studies, various descriptors were used to denote the management or type of habitat. “Idle” used as a modifier (e.g., idle tallgrass) denotes undisturbed or unmanaged (e.g., not burned, mowed, or grazed) areas. “Idle” by itself denotes unmanaged areas in which the plant species were not mentioned. Examples of “idle” habitats include weedy or fallow areas (e.g., oldfields), fencerows, grassed waterways, terraces, ditches, and road rights-of-way. “Tame” denotes introduced plant species (e.g., smooth brome [Bromus inermis]) that are not native to North American prairies. “Hayland” refers to any habitat that was mowed, regardless of whether the resulting cut vegetation was removed. “Burned” includes habitats that were burned intentionally or accidentally or those burned by natural forces (e.g., lightning). In situations where there are two or more descriptors (e.g., idle tame hayland), the first
descriptor modifies the following descriptors. For example, idle tame hayland is habitat that is usually mowed annually but happened to be undisturbed during the year of the study.
