(57) **ABSTRACT**

A system is provided for generating high-energy particles and for inducing nuclear reactions. The system includes a laser and for emitting a laser beam, an irradiation target for receiving the laser beam and producing high-energy particles, and a secondary target for receiving the high-energy particles, thereby inducing a nuclear reaction. A method is also provided including producing a laser beam of high-intensity with an ultra-short pulse duration, irradiating the laser beam onto an irradiation target in order to ionize the irradiation target and produce a collimated beam of high-energy particles, and colliding the collimated beam of high-energy particles onto a secondary target containing a nuclei, thereby inducing a nuclear reaction on the secondary target.

METHOD AND APPARATUS FOR HIGH-ENERGY GENERATION AND FOR INDUCING NUCLEAR REACTIONS

CROSS-REFERENCE TO RELATED APPLICATIONS

This application claims the benefit of U.S. Provisional Application No. 60/247,024, filed Nov. 8, 2000.

GOVERNMENT SUPPORT

This invention was made with government support under grant No. 8920108 awarded by the National Science Foundation.

FIELD OF THE INVENTION

The present invention relates generally to a method for generating high-energy particles using high-intensity short laser pulses and, more particularly, to a method for inducing nuclear reactions.

BACKGROUND OF THE INVENTION

There are a number of radioisotopes that are currently being utilized as markers and for other purposes in various medical, scientific, industrial and other applications. However, radioisotopes frequently have a relatively short half-life, from a few hours to a few minutes. Therefore it is generally desirable that such radioisotopes be either produced at the site where they are going to be utilized, or at a site relatively close thereto.

The short-lived radioisotopes are administered by intravenous injection or by having the subject inhale a gas containing small quantities of the radioisotope. Isotopes which are often incorporated into such gases or injection are carbon-11, nitrogen-13, oxygen, and fluorine-18. In Positron Emission Tomography (PET) facilities, these radioisotopes are derived from boron, carbon, nitrogen, and neon targets, respectively, by bombarding the targets with high-energy (approximately 6–30 MeV) protons or deuterons obtained from a particle accelerator.

The particle accelerator that is conventionally used to produce the isotope-generating particles is a cyclotron accelerator. Unfortunately, cyclotron accelerators suitable for use in the medical environment are very expensive (on the order of 1–2 million dollars), large and heavy (15–20 tons) and require a trained staff to operate and maintain the apparatus. Thus, the accelerator must be physically located in a medical center located within a short distance from the PET scanning apparatus.

Additionally, the high-energy particles produced by the cyclotron accelerator are generally used to bombard gas targets to obtain the isotopes. Gas targets must be separated from the high vacuum of the accelerator by a metallic foil window. Unfortunately, if the particles are accelerated with very high energies, the window is rapidly destroyed, thus increasing the cost of maintenance and requiring highly trained operators who must disassemble the device to replace the window.

Therefore, it is desirable to provide a method and apparatus for generating high-energy particles to induce nuclear reactions, thereby instantly producing radioisotopes. Moreover, it is desirable to provide such a method and apparatus that can be practically used for real-world medical applications and in low cost. For example, a method for generating high-energy ions would be beneficial for cancer hadron therapy because of the possible decrease in absorbed radiation.

SUMMARY OF THE INVENTION

The present invention provides a system for generating high-energy particles and for inducing nuclear reactions. The system includes a laser for emitting a laser beam, an irradiation target for receiving the laser beam and producing high-energy particles, and a secondary target for receiving the high-energy particles, thereby inducing a nuclear reaction. A filter and a monitor may be installed to estimate the energy of the high-energy particles, however these elements are not necessary to induce nuclear reactions and can be omitted.

The present invention also provides a method for generating high-energy particles and for inducing nuclear reactions. The steps of the method include producing a laser beam of high-intensity with an ultra-short pulse duration, irradiating the laser beam onto an irradiation target in order to ionize the irradiation target and produce a collimated beam of high-energy particles, and colliding the collimated beam of high-energy particles onto a secondary target containing a nuclei, thereby inducing a nuclear reaction in the secondary target.

Further areas of applicability of the present invention will become apparent from the detailed description provided hereinafter. It should be understood that the detailed description and specific examples, while indicating the preferred embodiment of the invention, are intended for purposes of illustration only and are not intended to limit the scope of the invention.

BRIEF DESCRIPTION OF THE DRAWINGS

The various features, advantages and other uses of the present invention will become more apparent by referring to the following description and drawings, wherein:

FIG. 1 is a schematic illustration of the apparatus for generating high-energy particles and for inducing nuclear reactions;

FIG. 2 is a flowchart illustrating the method for inducing nuclear reactions; and

FIG. 3 is a graph illustrating the relationship between laser intensity and maximum energy of generated ions.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The present invention is directed towards a method for generating high-energy particles which are then used to produce nuclear reactions. The method can supply X-ray, electron beam, ion beam and radioisotopes used in radiation therapy, medical radioisotope production, and material diagnostics. The present invention also makes nuclear devices available for applications such as medical diagnosis like positron emission tomography, material inspection, nuclear transformation, and nuclear reaction simulation.

Referring now to the drawings, FIG. 1 illustrates a laser and laser irradiation equipment **10** emitting a laser beam **12**. An irradiation target **14** is disposed downstream from the laser **10** and in radiation receiving relation to the beam **12**. The irradiation target **14** is comprised of a thin film **16**, such as a Mylar film having a thickness of about 10 micrometers, coated with a plastic layer **18**, such as a deuterated plastic layer.

Upon bombardment with the laser beam **12**, the irradiation target **14** produces a collimated beam of high-energy particles **20**. The high-energy particles **20** are accelerated toward a secondary target **22** disposed downstream of the

irradiation target **14**. The secondary target **22** contains nuclei and is enriched with, for example, boron-10 up to 90% in concentration, thereby inducing a nuclear reaction. This nuclear reaction allows for the production of radioisotopes and alpha particles. The secondary target **22** may also take the form of a patient in the case of radiation therapy such as cancer hadron treatment.

The secondary target **22** is preferably located axially offset from the irradiation target **14** and on the opposite side as the laser **10**. The secondary target **22** includes an activation region **24** where the nuclear reaction is localized. Although not required, the activation region **24** is preferably a planar member oriented normal to a central axis of the cone of high energy particles **20**.

Although the irradiation target **14** is illustrated as a thin film solid, gas jets can be used as the irradiation target **14**. For example, super sonic gas jets can be irradiated by the laser beam **12**. Moreover, the secondary target **22** enriched with boron-10 can be a solid, liquid jet, or a droplet jet target of some other element.

Referring now also to FIG. 2, the operation of the present invention will be described. At step **S0**, the laser and laser irradiation equipment **10** is turned on. In step **S1**, the irradiation target **14** is irradiated with the ultra-short high-intensity laser beam **12**. This results in the generation of high-energy particles **20** in step **S2**. In step **S3**, the high-energy particles **20** collide with the secondary target **22** containing nuclei in the activation region **24**. This induces a nuclear reaction in step **S4**. At step **S5**, the method ends or can be repeated.

Referring again to FIG. 1, the method will be described in greater detail. The laser and irradiation laser equipment **10** focuses a laser beam **12** on a small focusing area **26** on the irradiation target **14** by focusing optics. The laser beam **12** preferably has an intensity greater than 10^{18} W/cm², and a pulse duration shorter than 10 picoseconds. This allows for an instant production of particles with high energies.

The concentrated energy of the focused laser beam **12** ionizes the irradiation target **14** which raises the temperature of the target **14** and then produces plasmas that consists of free electrons and ions. The electrons are then expelled and accelerated from the small focusing area **26** to high energies by very strong electro-magnetic fields or light pressure from the laser beam **12**. The expelling may also be due to a plurality of traveling plasma waves induced by the laser beam **12** or stimulated scattering produced by the laser beam **12** hitting the irradiation target **14**. The small region **28** where plasmas are produced is preferably less than about 1 mm, thereby making it possible to obtain a radiation shielding area smaller than the radiation shielding areas required in conventional accelerators.

Once the electrons are expelled from the target **14**, the ions are left due to their large inertia. This produces a charge separation, which in turn produces an electric field. The ions having a pulse duration shorter than 10^{-9} are accelerated by the electric field to high energy levels, for example greater than 100 keV, due to the high intensity of the laser beam **12** that produces the large electric field. This results in the generation of high-energetic particles **20**.

The charge separation is sustained until electrons coming from the areas surrounding region **28** neutralize the charge separation. The direction of the high-energy ion emission is preferably limited within some angle, for example 40 degrees, around the normal direction of the surface **29** of the target **14**. This simplifies the use of the high-energy particles **20**.

Under the above circumstances, the electric field exceeds 10 GeV/cm. As such, the acceleration length is 5 to 6 orders of magnitude shorter than conventional accelerators. The number of ions accelerated exceeds 10^{10} particles, proving a peak current of a few kilo-amperes, which is 3 to 4 orders of magnitude higher than what conventional accelerators produce.

As described above, the high-energy particles **20** emitted toward the secondary target **22** placed behind the irradiation target **14** induce nuclear reactions. That is, the bombardment of the particles **20** on the secondary target **22** produces positron active isotopes. However, it should be noted that nuclear reactions are also capable of being induced within the irradiation target **14**, in which case the secondary target **22** can be omitted.

Laser beam **12** preferably has a pulse duration less than 10 pico-seconds. When the pulse duration is longer than 10 pico-seconds, the diffusion of ions produced by the laser beam **12** starts before the end of the laser beam **12**. Thus, the charge separation region **28** is not able to grow large enough to accelerate the ions up to a high energy level, which is desired. On the other hand, a pulse duration less than 10 pico-seconds makes for a larger charge separation, thus making a higher electric field, which is required for the production of high-energy particles **20**. The laser beam has a repetition rate greater than or equal to about 10^{-3} Hz.

FIG. 3 is a graph illustrating the relationship between the laser beam intensity (laser beam **12**) and the maximum energy of the generated ions (particles **20**). As can be seen, by irradiating the irradiation target **14** with the laser beam **12**, positive ions can be generated as high energy particles **20** and accelerated up to high energy levels such as 10 MeV. These levels are not attainable with conventional cyclotrons. Nonetheless, it is not always necessary to accelerate the high-energy particles **20** to 10 MeV. For example, 100 keV would be enough energy to accelerate certain particles to induce a nuclear reaction.

One type of laser and irradiation equipment **10** used is the hybrid Ti:Al₂O₃/Nd:phosphate glass CPA laser with a power of 10 TW. This type of laser is able to emit a laser beam **12** with 0.4 picosecond pulse duration and about 3 Joules of energy. To accomplish this, the laser **10** first stretches laser pulses emitted from an oscillator by a pulse stretcher, then amplifies these stretched pulses by amplifiers, and finally increases the peak intensity by compressing the pulse duration by a pulse compressor.

Thereafter, this ultra-short pulse with a high peak intensity is focused by focusing optics, and is irradiated onto the deuterated plastic layer **16** of the irradiation target **14**. The laser beam **12** can be irradiated onto the deuterated plastic layer **16** on the irradiation target **14** with a focusing diameter of 10 micrometers. Of course other types of lasers and irradiation equipment may be used.

Although not shown in the figures, shields can be placed around the activation region **28** in order to contain the radiation. Since the ultra-short pulse laser beam **12** is used to generate the high-energy particles **20** for inducing the nuclear reactions, the size of the entire above-described apparatus is relatively small. As such, any shield employed can be simple compared with the method of inducing nuclear reactions using nuclear reactors and accelerators.

The control of nuclear reactions is made easy by the present invention because nuclear reactions are induced by irradiation of the laser beam **12** from the laser and laser equipment **10**. The laser **10** preferably has an on/off feature that can start and stop the laser beam **12**, which is used for

the production of the nuclear reactions. Also, by adjusting the focusing intensity and the energy of the laser beam **12**, the energy of the generated high-energy particles **20** can be controlled, and therefore nuclear reactions can be controlled.

One way to detect the energy of the high-energy particles **20**, is by installing a filter **30** made of, for example, Polyethylene Terephthalate and a monitor **32**, shown in FIG. 1. Preferably, these elements are disposed downstream of the secondary target **22** on an opposite side as the irradiation target **14**. The filter **30** and the monitor **32** are used to estimate the energy of the high-energy particles **20** irradiated onto the secondary target **22**.

More particularly, only particles with certain energy levels will penetrate the entire thickness of the filter **30**. If the monitor **32** detects particles **20** behind filter **30**, then the particles **20** achieved a given energy or more. For example, energy of about 1 MeV is necessary for protons to penetrate the filter **30** with a 10 micron thickness. Therefore, when the monitor **32** detects protons, the proton energies are greater than 1 MeV. Of course, the filter **30** and the monitor **32** are not necessary to generate high-energy particles **20** or induce nuclear reactions and therefore do not have to be installed.

The production of radioisotopes by a nuclear fusion reaction with the present invention will now be discussed in greater detail. In this example, the plastic layer **16** of the target **14** is made of deuterated plastic. Further, the secondary target is made of boron-10.

Ion particles **20**, which are streams of positive ions, are emitted from target **14** with an angle of about 40 degrees. More particularly, the ion particles **20** irradiate from the deuterated plastic layer **16** on the irradiation target **14** and thus produce high energy ion particles **20** of deuteron. The high-energy deuteron particles **20** then collide with the boron-10 secondary target **22**. Thus, a nuclear reaction $10\text{B}(d,n)11\text{C}$ inside the secondary target **22** is induced. Because of this, carbon-11 (^{11}C), which is a radioisotope, and neutrons(n) are produced.

Usually, nuclear reactions are induced in the region **24** located between the surface **34** of the secondary target **22** and a depth of about 1 mm. Therefore, the produced carbon-11 absolutely remains inside the target **22**.

In another example, the deuterated plastic layer **16** can be omitted from the irradiation target **14**, and normal boron instead of boron-10, can be used as the secondary target **22**. In this case, protons are mainly generated as high-energy particles **20** when the laser beam **12** irradiates the irradiation target **14**. The nuclear reaction in this case, $11\text{B}(p,n)11\text{C}$, can be induced when the high energy proton particles **20** collide with the boron enriched secondary target **22**. Once again, carbon-11, which is a radioisotope, and neutrons are produced.

The produced carbon-11 is a pure positron emitter with a half-life of 20 minutes and can be used for diagnostics in medicine and defect diagnostics for materials. Carbon-11 is more manageable as a nuclear material than sodium-22 because the radioactivity of carbon-11 decays so much, even in one night due to its short half-life of 20 minutes. Carbon-11 of 2 nano-curie can be produced by one pulse with the aforementioned energy of the laser beam **12**. Carbon-11 of 10 micro-curie can also be produced when the laser beam **12** is irradiated with a 10-Hz pulse repetition rate for 1 hour. This radioactivity is the same level as that from a commercial sodium-22 as a calibration source.

Although the irradiation target **14** has been described as generating high-energy particles **20** by the laser beam **12**, high energy X-rays can also be generated. The high intensity

laser beam **12** passes through the irradiation target **14** and the generated X-rays are emitted in a direction normal to the surface **29** irradiated by the laser beam **12** and opposite the laser and laser irradiation equipment **10**.

When the X-rays have energies higher than 1.02 MeV, an electron and a positron can be produced. This is done through the interaction of the irradiation target **14** and other materials. Therefore, electrons, X-rays and positrons can be generated as high-energy particles **20**.

The high-energy particles **20** can also be positive ions that can induce nuclear fusion or nuclear fission with other materials inside the irradiation target **14**. Nuclear reactions such as (γ , n) can be induced by the gamma-rays generated from the above-mentioned nuclear reactions. This nuclear reaction can also produce isotopes and neutrons, which are used in medicine.

It should be understood that by changing the combinations of the materials of the irradiation target **14** and the secondary target **22**, many reactions other than the ones mentioned above, ($10\text{B}(b,n)11\text{C}$ and $11\text{B}(p,n)11\text{C}$), can be produced. As one example, by using a material containing hydrogen for the irradiation target **14**, protons (p) can be generated as the high energy positive ion particles **20**. By colliding these high energy proton particles **20** with a secondary target **22** containing nitrogen-14, the nuclear fusion $14\text{N}(p,\alpha)11\text{C}$ can be induced, and carbon-11, which is a radioisotope with a short half-life, and alpha particles can be produced.

Other combinations include colliding protons as the high energy particles **20** with a secondary target **22** containing oxygen-16. This can induce the nuclear fusion $16\text{O}(p,\alpha)13\text{N}$, and nitrogen-13, which is a radioisotope with a short half-life, and alpha particles can be produced. By colliding protons as the high energy particles **20** with a secondary target **22** containing oxygen-18, the nuclear fusion $18\text{O}(p,n)18\text{F}$ can be induced, and fluorine-18, which is a radioisotope with a short half-life, and neutrons can be produced. By colliding protons as the high energy particles **20** with a secondary target **22** containing boron, the nuclear fusion $10\text{B}(p,\alpha)7\text{Be}$ can be induced, and Beryllium-7, which is a radioisotope with a short half-life, and alpha particles can be produced. By colliding protons as high energy particles **20** with a secondary target **22** containing nitrogen-15, the nuclear fusion $15\text{N}(p,n)15\text{O}$ can be induced, and oxygen-15, which is a radioisotope with a short half-life, and neutrons can be produced.

By using an irradiation target **14** containing deuterium, deuterons are mainly generated as the high-energy positive ion particles **20**. Therefore, by colliding these high energy deuterons with a secondary target **22** containing carbon-12, the nuclear $12\text{C}(d,n)13\text{N}$ can be induced, and nitrogen-13, which is a radioisotope with a short half-life, and neutrons can be produced. By colliding deuterons as the high energy particles **20** with a secondary target **22** containing nitrogen-14, the nuclear fusion $14\text{N}(d,n)15\text{O}$ can be induced, and oxygen-15, which is a radioisotope with a short half-life, and neutrons can be produced. By colliding deuterons as the high energy particles **20** with a target **22** containing neon-20, the nuclear fusion $20\text{Ne}(d,\alpha)18\text{F}$ can be induced, and fluorine-18, which is a radioisotope with a short half-life, and alpha particles can be produced.

The energy of the particles **20** generated by the irradiation of the laser beam **12** (such as X-rays and positive ions) can be more than the threshold energy for nuclear fissions, so the nuclear reaction can be easily induced. For example, by using materials containing hydrogen as the irradiation target

14 and the materials containing uranium as the secondary target **22**, and by colliding the high energy proton particles **20** with 10 MeV onto the secondary target **22**, nuclear fission of uranium can be induced.

Additionally, by colliding the high-energy particles **20** generated from the irradiation target **14** onto the nuclei inside the secondary target **22**, the nuclei can be excited, thus producing a nuclear isomer. The nuclear isomer can change from an excited nuclear isomer state to a stable state, thus obtaining a gamma ray source with a line spectral profile, which can be developed into a gamma-ray laser.

Although the aforementioned examples are among the most used examples, there are many applications for using this invention. For example, although the irradiation target **14** and the secondary target **22** are different and separated in the examples above, the irradiation target **14** and the secondary target **22** can be merged, and a nuclear reaction can be induced with nuclei inside the common target irradiated by the laser beam **12**. In this case, the region where nuclear reaction is induced can be limited to the small region **28** close to the laser focusing area **26** irradiated by the laser beam **12**.

Moreover, although the high energy particles **20** are mainly protons and deuterons in the above mentioned examples, triton can be used, and a mixture of these particles can also be used. Further, the laser beam **12** can be irradiated onto the irradiation target **14** repetitively with a pulse interval shorter than the half-life of the products by nuclear reactions. Therefore, the amount of isotopes with a short half-life can be increased by accumulation.

The description of the invention is merely exemplary in nature and, thus, variations that do not depart from the gist of the invention are intended to be within the scope of the invention. Such variations are not to be regarded as a departure from the spirit and scope of the invention.

What is claimed is:

1. A method of generating a collimated beam of high-energy particles comprising:

producing a laser beam having an intensity greater than or equal to about 10^{18} W/cm² and a pulse duration less than or equal to about 10^{-9} seconds; and

irradiating an irradiation target capable of releasing high energy ions with said laser beam,

wherein said irradiation step produces a particle beam directed to within about 40 degrees of normal to said irradiation target.

2. A method of generating a collimated beam of high-energy particles comprising:

producing a laser beam having an intensity greater than or equal to about 10^{18} W/cm² and a pulse duration less than or equal to about 10^{-11} seconds; and

irradiating an irradiation target capable of releasing high energy ions with said laser beam.

3. A method of generating a collimated beam of high-energy particles comprising:

producing a laser beam having an intensity greater than or equal to about 10^{18} W/cm² and a pulse duration less than or equal to about 10^{-9} seconds; and

irradiating an irradiation target capable of releasing high energy ions with said laser beam,

wherein said laser beam has a repetition rate greater than or equal to about 10^{-3} Hz.

4. A method of generating a collimated beam of high-energy particles comprising:

producing a laser beam having an intensity greater than or equal to about 10^{18} W/cm² and a pulse duration less than or equal to about 10^{-9} seconds; and

irradiating an irradiation target capable of releasing high energy ions with said laser beam,

wherein said irradiation target further comprises one of a solid, a liquid jet, and a droplet jet.

5. The method of claim **3**, wherein said irradiation step produces a particle beam with an energy level greater than or equal to about 100 keV.

6. A method of generating a collimated beam of high-energy particles comprising:

producing a laser beam having an intensity greater than or equal to about 10^{18} W/cm² and a pulse duration less than or equal to about 10^{-9} seconds;

irradiating an irradiation target capable of releasing high energy ions with said laser beam; and

inducing a nuclear reaction by colliding said particle beam into a secondary target containing a nuclei.

7. The method of claim **6** wherein said secondary target is merged with said irradiation target.

8. The method of claim **6** wherein said particle beam includes at least one of protons, deuterons, and tritons.

9. The method of claim **6** wherein said secondary target further comprises at least one of boron, carbon, nitrogen, oxygen, and neon.

10. The method of claim **6** wherein said particle beam further comprises protons and said secondary target further comprises at least one of boron-11, boron-10, nitrogen-14, oxygen-16, nitrogen-15, and oxygen-18.

11. The method of claim **6** wherein said particle beam further comprises deuterons and said secondary target further comprises at least one of boron-10, carbon-12, nitrogen-14, and neon-20.

12. The method of claim **6** wherein said laser beam includes a pulse interval shorter than a half-life of isotopes produced by said nuclear reaction.

13. The method of claim **6** wherein said particle beam includes excited atomic nuclei.

14. An apparatus for generating a collimated beam of high-energy particles comprising:

a laser adapted to generate a laser beam having an intensity greater than or equal to about 10^{18} W/cm² and a pulse duration less than or equal to about 10^{-9} seconds; and

an irradiation target capable of releasing high energy ions disposed in irradiation receiving relation to said laser beam,

wherein said irradiation target further comprises one of a solid, a liquid jet, and a droplet jet.

15. An apparatus for generating a collimated beam of high-energy particles comprising:

a laser adapted to generate a laser beam having an intensity greater than or equal to about 10^{18} W/cm² and a pulse duration less than or equal to about 10^{-9} seconds;

an irradiation target capable of releasing high energy ions disposed in irradiation receiving relation to said laser beam; and

a secondary target containing a nuclei disposed downstream of said irradiation target and receiving a particle beam from said irradiation target to induce reaction.

16. An apparatus for generating a collimated beam of high-energy particles comprising:

a laser adapted to generate a laser beam having an intensity greater than or equal to about 10^{18} W/cm² and a pulse duration less than or equal to about 10^{-9} seconds; and

9

an irradiation target capable of releasing high energy ions disposed in irradiation receiving relation to said laser beam,

wherein said secondary target is merged with said irradiation target.

17. An apparatus for generating a collimated beam of high-energy particles comprising:

a laser adapted to generate a laser beam having an intensity greater than or equal to about 10^{18} W/cm² and a pulse duration less than or equal to about 10^{-9} seconds; and

an irradiation target capable of releasing high energy ions disposed in irradiation receiving relation to said laser beam,

10

wherein said particle beam includes at least one of protons, deuterons, and tritons.

18. An apparatus for generating a collimated beam of high-energy particles comprising:

a laser adapted to generate a laser beam having an intensity greater than or equal to about 10^{18} W/cm² and a pulse duration less than or equal to about 10^{-9} seconds; and

an irradiation target capable of releasing high energy ions disposed in irradiation receiving relation to said laser beam,

wherein said secondary target further comprises at least one of boron, carbon, nitrogen, oxygen, and neon.
