(Received 7 August 2006; published 27 October 2006)

A search for direct production of scalar bottom quarks (\tilde{b}) is performed with 310 pb^{-1} of data collected by the D0 experiment in $p\bar{p}$ collisions at $\sqrt{s} = 1.96 \text{ TeV}$ at the Fermilab Tevatron Collider. The topology analyzed consists of two b jets and an imbalance in transverse momentum due to undetected neutralinos ($\tilde{\chi}_1^0$), with $\tilde{\chi}_1^0$ assumed to be the lightest supersymmetric particle. We find the data consistent with standard model expectations, and set a 95% C.L. exclusion domain in the $(m_{\tilde{b}}, m_{\tilde{\chi}_1^0})$ mass plane, improving significantly upon the results from run I of the Tevatron.

Supersymmetric (SUSY) models [1] provide an extension of the standard model (SM) with mechanisms viable for the unification of interactions and a solution to the hierarchy problem. Particularly attractive are models that conserve R parity, in which SUSY particles are produced in pairs and the lightest supersymmetric particle (LSP) is stable. In SUSY, a scalar field is associated with each of the left- and right-handed chirality states of a given SM quark or lepton. Two mass eigenstates result from the mixing of these scalar fields. The spin-1/2 partners of the neutral gauge and Higgs bosons are called neutralinos.

In supergravity inspired models [2], the lightest neutralino $\tilde{\chi}_1^0$ arises as the natural LSP, and, being neutral and weakly interacting, could be responsible for the dark matter in the Universe. For large values of $\tan\beta$ (the ratio of the vacuum expectation values of the two Higgs fields) the mixing term among the scalar fields associated with the bottom quark is large. Therefore, a large splitting is expected among the mass eigenstates, that could result in a low mass value for one of them, hereafter called scalar bottom quark or sbottom (\tilde{b}). The SUSY particle mass hierarchy can even be such that the decay $\tilde{b} \rightarrow b\tilde{\chi}_1^0$ is the only one kinematically allowed [3], an assumption that is made in the following.

In this Letter, a search is reported for \tilde{b} pair production with 310 pb^{-1} of data collected during run II of the Fermilab Tevatron. At leading order, the \tilde{b} pair production cross section in $p\bar{p}$ collisions depends only on the sbottom mass. For a center-of-mass energy $\sqrt{s} = 1.96 \text{ TeV}$, the next-to-leading order (NLO) cross section, calculated with PROSPINO-2 [4] ranges from 15 to 0.084 pb for sbottom masses between 100 and 230 GeV, with very little dependence on the masses of the other SUSY particles. The final state of this process corresponds to two b jets and missing transverse energy (\cancel{E}_T) due to the undetected neutralinos. The maximum sbottom mass ($m_{\tilde{b}}$) excluded by previous results is 148 GeV [5].

A full description of the D0 detector is available in Ref. [6]. The central tracking system consists of a silicon microstrip tracker and a central fiber tracker, both located within a 1.9 T superconducting solenoid. A liquid-argon and uranium calorimeter covers pseudorapidities up to $|\eta| \approx 4.2$, where $\eta = -\ln[\tan(\theta/2)]$ and θ is the polar angle relative to the proton beam. The calorimeter has three sections, housed in separate cryostats: the central one

covers $|\eta| \leq 1.1$, and the two end sections extend the coverage to larger $|\eta|$. The calorimeter is segmented in depth, with four electromagnetic layers followed by up to five hadronic layers. It is also segmented into projective towers of 0.1×0.1 size in $\eta - \phi$ space, where ϕ is the azimuth in radians. An outer muon system, covering $|\eta| < 2$, consists of a layer of tracking detectors and scintillation trigger counters positioned in front of 1.8 T toroids, followed by two similar layers after the toroids. Jet reconstruction is based on the run II cone algorithm [7] with a cone size of 0.5, that uses energies deposited in calorimeter towers. Jet energies are calibrated using transverse momentum balance in photon + jet events. The missing transverse energy in an event is based on all calorimeter cells, and is corrected for the jet energy calibration and for reconstructed muons.

The D0 trigger has three levels: L1, L2, and L3. The data were collected with triggers specifically designed for \cancel{E}_T + jets topologies. We define $\cancel{H}_T = |\sum_{\text{jets}} \vec{p}_T|$ the vector sum of the jet transverse momenta. The trigger conditions at L1 require at least three calorimeter towers with $E_T > 5 \text{ GeV}$, where a trigger tower spans $\Delta\phi \times \Delta\eta = 0.2 \times 0.2$. We then require $\cancel{H}_T > 20$ (30) GeV at L2 (L3). Approximately 14×10^6 events were collected with the \cancel{E}_T + jets triggers.

The signal is simulated in the framework of a generic minimal supersymmetric standard model, in which we vary the masses of the \tilde{b} and $\tilde{\chi}_1^0$, all other parameters being fixed. The masses of the other SUSY particles are set such that the only sbottom decay mode is into $b\tilde{\chi}_1^0$. The SUSY and SM processes are processed using Monte Carlo (MC) generators PYTHIA 6.202 [8] for the signal, ALPGEN 1.3.3 [9] interfaced with PYTHIA for the SM. All the events are passed through a full GEANT-3 [10] simulation of the geometry and response of the D0 detector with an average of 0.8 minimum-bias events overlaid on each generated event. The CTEQ5L parton density functions (PDF) [11] are used in the simulation.

Instrumental background from mismeasurement of jet energies in multijet events is estimated from data, and is referred to as ‘‘QCD’’ background in the following. The main SM backgrounds relevant to our analysis are from vector boson production in association with jets, and top quark production. To estimate the backgrounds from W/Z + jets processes, we use the NLO cross sections computed with MCFM [12]. The theoretical NNLO $t\bar{t}$ production cross section is taken from Ref. [13].

The events are examined to ensure that the reconstructed vertex corresponds to the actual position of the primary vertex (PV). We select events that are well contained in the detector by restricting the PV within 60 cm along the beam direction with respect to the detector center. We define a charged-particle fraction (CPF) as the ratio of the charged-particle transverse energy, computed from the sum of scalar p_T values of charged particles (reconstructed in the tracking system) that emanate from the PV and are associated with a jet, divided by the jet transverse energy measured in the calorimeter. The two leading jets, i.e., those with the largest transverse energies, are required to have $\text{CPF} > 0.05$. This criterion rejects events with fake jets or where a wrong PV is selected. The overall inefficiency associated with this procedure is measured using events collected at random beam crossings, and events with two jets emitted back-to-back in azimuth. The jets must also have energy fraction in the electromagnetic layers of the calorimeter < 0.95 and $p_T > 30, 15$ GeV for the first and second leading jets. This set of initial cuts requires in addition $\Delta\phi < 165^\circ$, where $\Delta\phi$ is defined as the difference in azimuth between the two leading jets.

Table I defines our selection criteria, and shows the effect of applying them sequentially in the analysis of data, and their impact on signal efficiency, for the choice of $(m_{\tilde{b}}, m_{\tilde{\chi}_1^0}) = (140, 80)$ GeV. Criteria **C1-C4** are effective against QCD, **C2** and **C4-C8** against vector – bosons + jets, and **C9** suppresses $t\bar{t}$ background. For \tilde{b} masses of ~ 100 GeV, the mean \cancel{E}_T and jet p_T are close to what is expected from SM backgrounds, but are substantially larger for higher \tilde{b} masses. The selections are tuned on MC events so as to maintain good sensitivity to signal for small \tilde{b} masses, using minimal values for threshold requirements, for instance $\cancel{E}_T > 60$ GeV (**C1**) and $p_T > 40, 20$ GeV (**C2**) for the first and second leading jets. Later we show that, depending on the masses $(m_{\tilde{b}}, m_{\tilde{\chi}_1^0})$, higher thresholds on \cancel{E}_T and jet p_T can be applied to increase the sensitivity to signal.

TABLE I. Sequence of criteria applied for the selection of events with their corresponding impact on data and on signal efficiency (Eff.) for $(m_{\tilde{b}}, m_{\tilde{\chi}_1^0}) = (140, 80)$.

Selection criterion applied	Events left	Eff. (%)
C1 : $\cancel{E}_T > 60$ GeV	16 279	18
C2 : $p_{T1} > 40$ GeV, $p_{T2} > 20$ GeV	14 095	16
C3 : $ \eta_{\text{jet1}}^{\text{det}} < 1.1, \eta_{\text{jet2}}^{\text{det}} < 2.0$	9653	14
C4 : $35^\circ < \Delta\phi_{\text{min}}(\cancel{E}_T, \text{jets}) < 120^\circ$	3149	10
C5 : $\Delta\phi_{\text{max}}(\cancel{E}_T, \text{jets}) < 175^\circ$	2783	9
C6 : isolated electron veto	2059	9
C7 : isolated muon veto	1809	9
C8 : isolated track veto	756	7
C9 : 2 or 3 jets	671	6

The first and second leading jets are required to be in the central region of the calorimeter, $|\eta^{\text{det}}| < 1.1$ and 2.0 , respectively, (**C3**), where η^{det} is the jet pseudorapidity calculated with a jet origin at the detector center. Because of the central production of \tilde{b} events, these selections do not affect signal efficiency, but reduce background. We also define $\Delta\phi_{\text{min}}(\cancel{E}_T, \text{jets})$ and $\Delta\phi_{\text{max}}(\cancel{E}_T, \text{jets})$, the minimum and maximum of the differences in azimuth between the direction of \cancel{E}_T and the direction of any jet. Requiring $\Delta\phi_{\text{min}} > 35^\circ$ rejects QCD events (**C4**), and $\Delta\phi_{\text{min}} < 120^\circ$ and $\Delta\phi_{\text{max}} < 175^\circ$ suppress SM background (**C4, C5**).

Since we do not expect isolated electrons, muons, or tau leptons in signal events, vetoes are imposed on events with an isolated electron (**C6**), muon (**C7**), or a charged track (**C8**) with $p_T > 5$ GeV. Electrons and muons are defined isolated based on a criterion for energy deposition in a cone around the lepton direction in the calorimeter. A charged track is considered isolated if no other charged track with $p_T > 1.5$ GeV is found in a hollow cone with inner and outer radii 0.05 and 0.2, formed around the direction of the track. The last requirement (**C9**) stipulates that either two or three jets are allowed.

Table II gives the numbers of events expected for SM backgrounds and signal, and the number of events observed in data after the above selections. Since an important fraction of the background corresponds to processes with light-flavor jets in the final state, we take advantage of the presence of b jets in the signal to significantly increase the sensitivity of the search by using a lifetime-based heavy-flavor tagging algorithm (b tagging). Based on the impact parameters of the tracks in the jet, the algorithm [14] computes a probability for a jet to be light flavored.

We select the b -tagging probability such that 0.1% of the light-flavored jets are tagged for jets having p_T of 50 GeV as yielding the best expected signal sensitivity. The corresponding typical tagging efficiencies for c - and b -quark jets are 5% and 30%, respectively. Because the current detector simulation does not reproduce the tracking precisely enough, the b -tagging algorithm is not applied to simulated jets directly. Instead, jets are weighted by their probability to be b tagged, according to their flavor, using parameterizations derived from data. In what follows, we require at least one b -tagged jet in the event. Requiring more than one b -tagged jet would lower slightly the sensitivity of the analysis.

In order to estimate the background from QCD, we compare our selected data sample, without imposing the criterion on \cancel{E}_T (**C1**), to the simulation of background from SM. Figure 1 shows that data are well reproduced by the SM background at high \cancel{E}_T . We therefore attribute the exponential rise at low \cancel{E}_T to QCD multijet instrumental background. A fit by an exponential to the data for $\cancel{E}_T < 60$ GeV, after subtraction of the contributions from the SM, is shown in the insert in Fig. 1. When the fit is

TABLE II. Numbers of events expected from SM and QCD backgrounds, of data events observed, and of signal events expected, after all selection criteria, both before (N_{exp}) and after b tagging. All uncertainties are statistical only. Backgrounds from b , c , and light jets (j) are shown separately.

SM process	N_{exp}	With b tagging
$W(e\nu + \mu\nu) + j\bar{j}$	155 ± 13	1.9 ± 0.2
$W(e\nu + \mu\nu) + cj$	2.2 ± 0.6	0.2 ± 0.1
$W(e\nu + \mu\nu) + b\bar{b}$	1.1 ± 0.1	0.6 ± 0.1
$W(\tau\nu) + \geq 1\text{jet}$	101 ± 14	4.1 ± 0.6
$W(\tau\nu) + b\bar{b}$	2.2 ± 0.3	1.0 ± 0.1
$Z(\nu\bar{\nu}) + j\bar{j}$	257 ± 12	3.9 ± 0.2
$Z(\nu\bar{\nu}) + c\bar{c}$	8.0 ± 0.7	0.9 ± 0.1
$Z(\nu\bar{\nu}) + b\bar{b}$	7.8 ± 0.3	4.0 ± 0.2
WW, WZ, ZZ	14.2 ± 0.7	0.9 ± 0.2
top production	7.9 ± 0.2	3.8 ± 0.2
Total SM	556 ± 23	21.5 ± 0.8
QCD background	109 ± 9	4 ± 2
Data	671	22
$(m_{\tilde{b}}, m_{\tilde{\chi}_1^0}) = (140, 80)$ GeV	43 ± 2	23.1 ± 0.9

extrapolated to $\cancel{E}_T > 60$ GeV, it provides an estimate of 109 ± 9 QCD events. After b tagging, this procedure estimates the presence of only 4 ± 2 events. Given the larger \cancel{E}_T threshold we use for higher sbottom masses, we expect that, after the b tagging, less than two QCD events will survive the final event selection. The QCD contribution is therefore neglected in the rest of this analysis. Table II shows the results after all selections, including b tagging, for SM backgrounds, data and signal.

FIG. 1 (color online). Distribution in \cancel{E}_T after applying all criteria, except $\cancel{E}_T > 60$ GeV (C1). The dark shaded area corresponds to the SM simulation. A fit by an exponential to $\cancel{E}_T < 60$ GeV, after subtraction of the contributions from the SM, shown in the figure insert, is used to estimate the instrumental background.

As already mentioned, the mean \cancel{E}_T and jet p_T become substantially larger for higher sbottom masses than the values expected from SM backgrounds. This provides a handle for improving the sensitivity to the signal for large $m_{\tilde{b}}$. Table III shows results for two higher sbottom-mass points, the chosen \cancel{E}_T and p_T thresholds, together with the resulting number of events found after all selections, including b tagging, for data, SM background, and signal. For the highest sbottom masses probed, we note a deficit in the number of events observed compared to the SM background expectation. The probability of such a deficit is 4%.

The following systematic uncertainties are taken into account in deriving the final results. The integrated luminosity contributes an uncertainty of 6.5%. The uncertainty from jet energy calibration is typically of the order of 7%. The total uncertainty from jet energy resolution, jet track confirmation, misvertexing and jet reconstruction is 5%. The systematic uncertainties from NLO cross sections in the SM backgrounds are estimated to be 15%. The effect of the choice of PDF on signal efficiencies is evaluated using the CTEQ6.1M PDF error set [15] resulting in a 8% uncertainty. The uncertainty from MC statistics can reach 10% for the SM and 5% for signal. The total uncertainty from isolated electron, muon, and track vetoes is 9%. The uncertainty from heavy-flavor tagging is 12% for SM and 8% for signal. Finally, the uncertainty from the trigger efficiency is 5%.

Since we do not observe any excess in the data relative to the expectations from SM backgrounds, we set limits on the production of sbottom quarks. Observed and expected 95% confidence level (C.L.) cross section upper limits are obtained using the modified frequentist approach [16], with correlations included between systematic uncertainties. The NLO \tilde{b} pair production cross section is subject to theoretical uncertainties arising from the PDF and from the renormalization and factorization scale choices. For a \tilde{b} mass of 200 GeV, a 16% PDF uncertainty is evaluated using the CTEQ6.1M PDF error set, and a 12% uncertainty is found by varying the scale by a factor of 2 up or down. For a given neutralino mass, a sbottom mass limit is obtained where the cross section upper limit intersects

TABLE III. Optimized values for the criteria C1 and C2, numbers of data events observed, numbers of events expected from SM and signal for two $(m_{\tilde{b}}, m_{\tilde{\chi}_1^0})$ masses after b tagging (statistical uncertainties only).

$(m_{\tilde{b}}, m_{\tilde{\chi}_1^0})$ in GeV	(180,90)	(215,0)
C1: \cancel{E}_T [GeV]	60	80
C2: jet 1 p_T [GeV]	70	100
C2: jet 2 p_T [GeV]	40	50
Data	7	0
SM	8.9 ± 0.3	3.2 ± 0.2
Signal	9.4 ± 0.3	4.6 ± 0.1

FIG. 2 (color online). Excluded regions at the 95% C.L. in the sbottom and neutralino mass plane. The new region excluded by this analysis is shown in dark shading. The dashed line corresponds to the expected limit. Regions excluded by previous experiments are also displayed in the figure [5].

the production cross section reduced by these uncertainties combined in quadrature. The results are summarized in the 95% C.L. exclusion contours displayed in Fig. 2. At higher sbottom masses, no events are observed where about three are expected, leading to an observed limit more constraining than expected.

In summary, this analysis represents the first Tevatron run II search for pair production of scalar bottom quarks. The exclusion contour we obtain is substantially more restrictive than the ones published with run I Tevatron data. With the current analysis using 310 pb^{-1} , the maximum $m_{\tilde{b}}$ excluded is 222 GeV, an improvement of more than 70 GeV with respect to previous results, and the most restrictive limit on the sbottom mass to date.
