HIGHLIGHTS

- Impacts of a hypothetical insecticide on ecosystem services provided by a lake were modeled.
- Complex response of fishing services due to non-linear feedbacks in the lake food web
- Water clarity increased with reduced insecticide use → increase in value by waders and swimmers.
- Models can generalize to meaningful endpoints and facilitate quantitative scenario comparison.

insecticide could affect aquatic species populations (e.g., recreational fish abundance) and environmental properties (e.g., water clarity) that would in turn affect delivery of ecosystem services. Different results were observed for different species of fish, thus the decision to manage the use of the insecticide for ecosystem services derived by anglers depends upon the favored species of fish. In our hypothetical shallow reservoir, water clarity was mostly driven by changes in food web dynamics, specifically the presence of zooplankton. In contrast to the complex response by fishing value, water clarity increased with reduced insecticide use, which produced a monotonic increase in value by waders and swimmers. Our study clearly showed the importance of considering nonlinear ecosystem feedbacks where the presence of insecticide changed the modeled food-web dynamics in unexpected ways. Our study highlights one of the main advantages of using ecological models for risk assessment, namely the ability to generalize to meaningful levels of organization and to facilitate quantitative comparisons among alternative scenarios and associated trade-offs among them while explicitly accounting for different groups of beneficiaries.

1. Introduction

Ecosystems provide various goods and services to human beneficiaries. These include food and water, flood protection, climate regulation, and recreational opportunities (Fisher et al., 2009). Processes at the population, community, and ecosystem scale contribute to various degrees to the delivery of ecosystem services (Luck et al., 2003). At the same time, anthropogenic activities can potentially affect different ecosystems and components adversely, thus interrupting service delivery (Johnston et al., 2015; Tilman et al., 2017). Assessing and managing risks of anthropogenic activities to ecological systems is necessary to ensure sustained delivery of ecosystem services for future generations.

Ecological risk assessment quantifies potential impacts on different receptors (e.g. species), and typically focuses on individual responses of a small set of representative species (Hommen et al., 2010). However, when assessing potential environmental risks from chemicals, we are interested in how chemicals might affect higher levels of organization, such as populations (Efroymson et al., 2004), habitats (Efroymson et al., 2010), ecological communities (Suter et al., 1999), ecosystems and the services that they provide (Nienstedt et al., 2012).

When considering ecosystem services, relevant assessment endpoints may be at the population or community level. Standard toxicity testing, the basis for chemical risk assessments, relies on testing a handful of species and focuses on effects at the individual level (Forbes and Galic, 2016). For example, in freshwater ecosystems phytoplankton, invertebrates and fish are often used as test organisms (Hommen et al., 2010). Even though impacts on their survival, growth, and reproduction are rigorously quantified and are assumed to be protective, these organisms and corresponding endpoints do not directly represent services that are valued by beneficiaries. Rather, beneficiaries may care about clean drinking water, clean water for recreation (swimming and boating), harvestable fish populations, and simply the aesthetic enjoyment of experiencing freshwater ecosystems (Dodds et al., 2008; Postel and Carpenter, 1997; Viscusi et al., 2008).

Ecological models provide a means of quantitatively linking measured risk assessment endpoints with protection goals (Forbes and Galic, 2016; Forbes et al., 2017). By integrating potential chemical effects with species life history, ecological interactions, environmental drivers and other potential stressors, we can predict long-term risks to ecological entities that deliver valued ecosystem services (De Laender and Janssen, 2013; Galic et al., 2012). Furthermore, we can easily and inexpensively evaluate multiple management options and quantify trade-offs among multiple services (Bennett et al., 2009).

The aim of this study was to demonstrate how an ecosystem modeling approach can be used to quantify insecticide-induced impacts on ecosystem services from organism-level toxicity data. The case study was developed as one of the outputs of a National Institute of Mathematical and Biological Synthesis (NIMBioS) working group hosted by the University of Tennessee in Knoxville (http://www.nimbios.org/workinggroups/WG_o2e). It represents an example of a recently-

developed framework for extrapolating impacts of chemicals from individual organisms to ecosystem services (Forbes et al., 2017).

The approach taken here was to quantify the benefits derived from a Midwestern US lake relative to potential effects of a hypothetical insecticide across a range of exposure scenarios, based on possible mitigation measures. We purposefully applied exposure scenarios that ensured a large disruption to the lake ecosystem to observe and quantify impacts on ecosystem services and any associated trade-offs. A well-tested lake ecosystem model was used to simulate the effects of a hypothetical insecticide on sensitive aquatic crustaceans and fish species. The main beneficiaries of ecosystem services were identified and provided by a generic lake in the Midwestern US as recreational fishers, swimmers and boaters. We focused on final ecosystem goods and services (FEGS), i.e., those directly used or enjoyed by beneficiaries (Boyd and Banzhaf, 2007; Bruins et al., 2017). A distinction is made between final (direct) and intermediate (indirect) ecosystem services. For example, most supporting services such as primary production or nutrient cycling are intermediate because, although they are not directly valued by the public, they support populations of game fish that are directly valued.

By simulating a range of exposure patterns, we illustrated how risks from exposure to this hypothetical insecticide could affect aquatic species populations (e.g., recreational fish abundance) and environmental properties (e.g., water clarity) that would in turn affect delivery of ecosystem services. We used a publicly available aquatic ecosystem model AQUATOX (Park et al., 2008), supported by the US Environmental Protection Agency. This model integrates environmental fate of chemicals and their impacts on generic and specific food webs in aquatic environments. It may be used for assessing impacts on aquatic ecosystems (Clough et al., 2017; Park et al., 2008), and a number of site- and condition-specific scenarios exist that are readily available to use.

Impacts were translated on ecological entities to changes in services delivered to beneficiaries, and benefits transfer methods were used to assign economic values to them (Richardson et al., 2015). We further assumed that certain mitigation measures (e.g., changes in insecticide application rate or frequency or presence of buffers) would change the insecticide loading that reaches the lake food web. We compared several management options to demonstrate how applying a biophysical model can advance our capabilities beyond risk assessment, i.e., to inform decision-making to improve the management of ecosystems facing various pressures from anthropogenic activities.

2. Methods

2.1. AQUATOX model

AQUATOX is an aquatic ecosystem simulation model, which was developed by the US Environmental Protection Agency, that links the physical or abiotic environment (i.e., water quality) and aquatic communities (Park et al., 2008). In this process-based mechanistic model, different communities are represented as compartments of biomass

that change based on the gains and losses defined for each group. In a series of linked differential equations, biomass is gained through growth, reproduction and external inflow, whereas biomass is lost through natural mortality, respiration, predation, exposure to toxicants, and emigration. The model also simulates cycling of all major nutrients, oxygen dynamics, and different fate processes for organic toxicants (Fig. 1). By simultaneously computing important chemical and biological processes over time, the model helps to identify cause-effect relationships between chemical water quality, the physical environment, and aquatic communities.

AQUATOX version 3.1 has been applied to simulate multiple environmental stressors (including nutrients, organic loadings, sediments, chemicals, and temperature) and their effects on algal, macrophyte, invertebrate, and fish communities. Various model applications have represented different aquatic ecosystems, including vertically stratified lakes, reservoirs and ponds, rivers and streams, and estuaries (Clough et al., 2017).

Appendix B of Park and Clough (2014) includes the full list of point-estimate parameters describing biota, chemicals, sites, and remineralization, their units, and their manner of reference in the AQUATOX software interface. The AQUATOX model is written in object-oriented Pascal using the Delphi programming system for Windows. As part of a case study scenario, initial conditions are set for state variables. Site characteristics and any parameter estimates that differ from AQUATOX default values are specified as part of each scenario. Details on the equations in AQUATOX, its developmental history, and use are provided in the technical documentation (Park and Clough, 2014).

2.2. Case study description

We chose to model the aquatic ecosystem of a generic reservoir in the Midwestern US for this case study because such lake systems are popular recreation destinations and therefore offer an opportunity to evaluate potential tradeoffs among ecosystem services (Fig. 2). As a starting point, we focused on a well-studied system, but modified it to

represent a clear reservoir that would increase its attractiveness to the public. We identified Coralville Reservoir (CR), which we used as a template to build a simulation model for a generic shallow reservoir in Johnston County, Iowa (USA). It is also one of the study files that is included in the installation of the AQUATOX software. Coralville Reservoir is a run-of-river reservoir that is influenced by agricultural runoff (Schnoor, 1981). As a result, the reservoir often experiences high turbidity that substantially limits phytoplankton growth. Simulations of toxicant impacts on zooplankton with original CR parameters did not cause substantial changes in biomass of phytoplankton or in turbidity because the influence of inorganic solids (i.e., silt from agricultural lands) was so dominant. Therefore, we restricted that influence to represent a reservoir/lake without substantial riverine inputs of suspended inorganic solids.

The approach to parameterization included an iterative process of adjusting a few parameters for site characteristics and biota to achieve a model reservoir in which phytoplankton dominate over submerged aquatic macrophytes, and an impact on herbivorous zooplankton leads to higher biomass of phytoplankton. The food web used in our lake model included four species of forage fish (bluegill, shad, catfish, and buffalofish), two piscivorous fish species (walleye and largemouth bass), four zooplankton functional taxa (daphnids, rotifers, copepods, and predatory zooplankton, i.e. *Chaoborus*), three benthic/epiphytic functional taxa (chironomids, Tubifex, and sphaerids), and four phytoplankton taxa (diatoms, dinoflagellates, and green and blue-green algae) (Forbes et al., 2017 – Fig. 3; Fig. 1). This is a realistic food-web dynamic in small lakes and reservoirs (Carpenter et al., 2010; Carpenter et al., 1985) and provides an opportunity to examine tradeoffs among ecosystem services. A more detailed description of these modifications, as well as the information on initial conditions, can be found in the Supplementary Information (Table SI 1 and SI 3). Due to our modifications, in the following we refer to this model system as the “case study reservoir”.

For this case study, we assumed that the reservoir is exposed to a hypothetical organophosphate insecticide. For simulation purposes, we used available toxicity data for a representative organophosphate

Fig. 1. Conceptual representation of different compartments represented in AQUATOX.

Fig. 2. Final ecosystem goods and services (FEGS) provided by a reservoir lake, representative of Midwestern lakes, and their beneficiaries.

insecticide that is registered for use on corn, which is the predominant crop in the watershed of the Coralville Reservoir. The case study chemical was slightly mobile in soil ($K_{oc} = 6040$ L/kg organic C) and moderately persistent (aerobic soil metabolism $t_{1/2} = 170$ d). The most sensitive taxa to this insecticide include zooplankton, especially cladocerans (i.e. *Daphnia* sp.), and pan fish, such as bluegill, followed by wall-eye and largemouth bass. Catfish and buffalo fish were the least sensitive. AQUATOX implements acute (mortality) and chronic (growth and reproduction) toxicity data in concentration-effects functions to simulate chemical impacts on biomass of different taxa (Park and Clough, 2014). We used surrogate species for those for which toxicity data were lacking; a table with all toxicity parameters used in this case study can be found in the Supplementary Information (Table SI 2). We made the conservative assumption that all agricultural land in the watershed was used for growing corn, i.e., ~57% of the total watershed area (www.nrcs.usda.gov/Internet/FSE_DOCUMENTS/nrcs142p2_006352.pdf). Water concentrations of the case study insecticide loading were modeled using the Pesticide Root Zone Model (PRZM, version 5.0) (<https://www.epa.gov/exposure-assessment-models/przm-version-index>) and the Variable Volume Water Model (VVWM), assuming label-rate insecticide application to all corn acreage (applied at 1.68 kg active ingredient/ha, twice per year) in the Coralville Reservoir watershed. PRZM is a simulation model that takes into account rainfall and evapotranspiration, as well as agricultural practices, to calculate daily fate of the pesticide in the field. Each PRZM scenario can be a unique combination of climatic conditions, crop-specific management practices, soil-specific properties, site-specific hydrology, and pesticide-specific application and dissipation processes (Young and Fry, 2016). Simulation outputs are daily edge-of-field runoff and spray drift loadings of pesticide which are discharged into a standard water body simulated by the VVWM (Young, 2016). This model simulates daily pesticide concentrations accounting for the processes of volatilization, sorption, hydrolysis, biodegradation, and photolysis.

Historical simulations were conducted for the period between October 1969 and September 1978 – the choice of the simulation period was driven by the availability of weather profiles in the original AQUATOX template. The same weather profiles were used to generate insecticide concentrations in PRZM and VVWM. We further simulated several management scenarios (MS) by reducing insecticide loading by different amounts. This was done assuming a reduced pesticide load (i.e. 10×, 25× or 100×), but the same temporal exposure pattern. We simulated the following management scenarios: no reduction (MS 0), a 5× reduction (MS 5), a 10× reduction (MS 10), a 25× reduction (MS 25), a 100× reduction (MS 100), and a complete absence of the insecticide (MS No pesticide). Management scenarios represent a reduction in total loading of the insecticide into the watershed through a combination of relevant mitigation measures. Conceptually, a given management scenario may be achieved through a combination of actions, including reduced application rates, fewer applications per field (not tested in this study) or use of riparian buffers; however, this analysis does not quantify impacts of specific actions on loading.

2.3. Selection and valuation of ecosystem services

For this case study, ecosystem services were identified using U.S. EPA's Final Ecosystem Goods and Services Classification System, or FECS (Landers and Nahlik, 2013). The FECS classifies environments and the corresponding ecological components that are directly enjoyed by different classes of beneficiaries.

Ecosystem services relevant to Midwestern reservoirs included the ability to view the lake bottom in wading areas, abundance of game fish, and water suitability for swimming (Table 1). We then identified corresponding metrics that could be estimated using AQUATOX outputs (Table 1). Finally, we selected abundance of game fish and water suitability for recreational purposes for economic valuation which was

Table 1

Framework for economic valuation of changes in final ecosystem goods and services (FEGS) across case study scenarios. Abbreviations are: final ecosystem goods & services (FEGS), FEGS classification system (FEGS-CS), and willingness-to-pay (WTP).

FEGS		Beneficiary		Available benefit transfer data	Corresponding model endpoint
From FEGS-CS	In case study	From FEGS-CS	In case study		
Presence of the environment/water suitability for swimming	Mean seasonal Secchi depth (m) ^a	Recreational/waders, swimmers, and divers	Recreational users of the case study reservoir	WTP (Iowans' travel to Iowa lakes) for change in water clarity = $\$0.21 \text{ m}^{-1} \text{ household}^{-1} \text{ lake}^{-1} \text{ y}^{-1}$ (Egan et al., 2009)	Change in seasonal Secchi depth (m) in different management scenarios
Presence of the environment/ability to view subsurface environment	Mean seasonal Secchi depth (m) ^a	Recreational/experiencers and viewers	General public and property owners at the case study reservoir	This FEGS was assumed to overlap with the previous one	Change in Secchi depth (m)
Fish/abundances of game fish	Biomass of several fish species	Recreational/anglers	Recreational anglers of the case study reservoir	WTP (Michigan anglers' travel to Michigan rivers, streams, impoundments) per additional fish caught = \$1.55 for panfish, \$1.57 for largemouth bass, \$4.03 for walleye (Melstrom et al., 2015)	Change in biomass of the four species of interest for angling: largemouth bass, walleye, bluegill, catfish

^a Secchi depths are defined as the number of meters beneath the surface of the water where a Secchi disk is visible.

conducted using the benefits transfer method (Richardson et al., 2015). This required us to assume that the transferred values pertain to this case study and that the demographics of beneficiaries are similar. Below we describe valuation methods for abundance of game fish and the suitability of a water body for wading or swimming.

2.3.1. Abundance of game fish

To illustrate valuation of this ecosystem service, the potential for fishing in the reservoir was translated from fish biomass (ρ) generated by AQUATOX to value (V) in dollars of a specific MS (i) of the insecticide loading (i.e., 25× decrease, 10× decrease, no insecticide use in the watershed). The focus of this analysis was on an annual change in the value of fishing that could be attributed to a specific type of fish (i.e., bluegill, bass, walleye or catfish). An annual time step (t) seemed most realistic for the time frame in which watershed and reservoir managers could collect data (e.g., crop practices, number of anglers visiting the reservoir, etc.) and make decisions.

For each type of fish, daily biomass values were generated by AQUATOX (dry weight) for the baseline scenario (i.e., insecticide use as on label) and for the three management scenarios. These values were then converted from a dry to a wet weight (U.S. Environmental Protection Agency, 1993). The daily change in biomass attributed to a management scenario was calculated as the difference between the biomass in the management and baseline scenarios. For each of the simulated full years (1970–1977), an average daily change in biomass ρ was calculated (Eq. (1)) for each year t and type of fish i :

$$\Delta \bar{\rho}_i = \frac{1}{365} \sum_{t=1}^{365} (\rho_{i,t} - \rho_{base,t}) \quad (1)$$

For each year and each type of fish, the value of an insecticide management scenario ($\$$; V_i ; Eq. (2)) was calculated by multiplying the daily change in density by willingness of fishers to pay (WTP) for a change in fish biomass and the number of visits to the lake per year (N)

$$V_i = \Delta \bar{\rho}_i \times WTP \times N \quad (2)$$

There were 187,382 visits to the reservoir in 2012 for fishing (U.S. Army Corps of Engineers, 2014), and we used 187,000 as the value for all simulation years in further analyses. WTP data used in this analysis were expressed as average cost (\$) per trip per kg/ha increase in a given type of fish. We assumed that all trips were attributed to a single species and that there were no species preferences, i.e., trips were not taken to fish for a specific species. This allowed us to weigh all species

equally for comparison. We used the following WTP: \$1.55 for bluegill (type of panfish), \$1.57 for largemouth bass and \$4.03 for walleye (Melstrom et al., 2015). Comparable WTP data for the Midwest were not found for catfish; however, some sources suggest that catfish may be valued at a similar level as panfish and bass and half of the value of walleye (Charbonneau and Hay, 1978). We, therefore, used the cost per trip value of \$1.55, which corresponds to bluegill, as a surrogate for catfish.

2.3.2. Water suitability for wading or swimming

The goal of this analysis was to illustrate a valuation of improved water clarity in the simulated reservoir. Water clarity is an important ecosystem service that is valued by different types of beneficiary (Fig. 2), including swimmers, boaters, and property owners; it has been identified as the best measure of high-quality water (Kosten et al., 2009; Peeters et al., 2009). Surveys show that clear water, measured by how many meters beneath the surface of the water a Secchi disk is visible, is highly valued by the general public (Schuetz et al., 2001). This is because the public has an intuitive understanding of what it means, and that it is a single aggregated measure reflecting a range of watershed impairments leading to eutrophication or high suspended sediment concentrations. A positive hyperbolic relationship exists between water clarity and an index of water quality (based on several parameters, incl. dissolved oxygen, pH, total phosphorus, nitrates, turbidity) (Ge et al., 2013). There is a threshold increase at relatively low Secchi depths (<1 m), which means that small increases in Secchi depths will yield large increases in perceived water quality. Secchi depths were generated in AQUATOX simulations for the scenarios described in the Case Study Description (Section 2.2). Our valuation considered the impact of management scenarios on the hypothetical insecticide. We examined the literature to determine what expressions of Secchi depth (SD) should be used to evaluate FEGS for recreational users of the modeled lake.

We relied on a water clarity valuation model developed using 2002 water quality data and a survey of Iowa households to quantify recreational visits to Iowa lakes in the same year (Egan et al., 2009). The resulting logistic model linked two responses: 1) the change in number of visits to lakes and 2) willingness-to-pay (WTP, 2009\$US/household) for increasing water clarity associated with a set of unimpaired lakes (annual median Secchi depth = 1.27 m) compared to impaired lakes (annual median Secchi depth = 0.81 m). From this, we estimated a marginal value (per-meter increase in Secchi depth). We then summarized our simulated data for April–October, which is assumed to be the time period representative of the recreational season for swimmers and

boaters. From that, we calculated median Secchi depths for each simulated year and scenario. From changes in clarity (differences in median Secchi depth between impaired and non-impaired lakes) we estimated changes in the number of trips and value per household. Water clarity is appreciated regionally, so the above estimates of value per household were expanded by estimating the number of households likely to visit the reservoir. The 2009 US Census estimated 55,967 households for Johnston County (where Coralville Reservoir is located), representing 4.2% of Iowa households (www.census.gov/2010census/popmap/ipmtext.php?fl=19). The WTP data based on annual Secchi depth values were the only data available to us, and using these data for the valuation of our seasonal patterns is a clear limitation of this analysis. Ideally, we would prefer to use a value representative of the recreational period (e.g., median values representing Secchi depths from April–October).

3. Results

3.1. Ecosystem dynamics under exposure to a hypothetical insecticide

Exposure to insecticide concentrations resulting from loadings provided by PRZM had substantial impacts on several taxa in the food web/ecosystem (relative to a scenario with no pesticide; Fig. 3). We show only a subset of compartments that AQUATOX simulated. Under the no management scenario (MS 0), biomass of daphnids, bluegill sunfish, and largemouth bass were kept low. Conversely, biomasses of phytoplankton and catfish benefitted from insecticide exposure and both increased. By applying different management scenarios that reduced

exposure concentrations, we found concentration–response relationships that differed among taxa. For the majority of taxa, a 25× reduction in insecticide exposure (MS 25) yielded biomass values that did not visibly differ from those in which no insecticide was assumed (MS No pesticide). Bluegill biomass was reduced even at 100× reduction in exposure (MS 100, as compared with MS No pesticide), whereas catfish biomass declined as insecticide exposure decreased. In further analyses, we show only scenarios with no management (MS 0), with 10× reduction (MS 10), with 25× reduction (MS 25) and the scenario with no insecticide (MS No pesticide).

Catfish, bluegill sunfish, and largemouth bass experienced very different dynamics due to exposure in the four management scenarios (Fig. 4). We compared biomass in different scenarios to the scenario without any exposure (MS No pesticide). Bluegill biomass declined almost instantly after exposure to the insecticide and did not recover in the three management scenarios with partial reduction of insecticide loading. Biomass of largemouth bass was almost zero in the no management scenario and dropped substantially in MS 10 after 3 years of exposure, with a subsequent recovery after 3 additional years. Biomass dynamics of both largemouth bass and walleye were similar and consistently higher through the simulation period in MS 25 than in MS No pesticide (Fig. 4). Biomass of catfish consistently declined with reductions in exposure (MS 0 > MS 10 > MS 25 > MS No pesticide).

Secchi depths varied across years and management scenarios (Fig. 5). The lower variability in 1969 was due to the simulation period capturing only the last 31 days of the season when the exposure concentrations were low, i.e. treatments were almost identical to controls for any management scenario. The exposure was high enough to

Fig. 3. Biomass of different compartments in the lake ecosystem, under management scenarios (MS) described in the legend. Box plots represent biomass across the whole duration of the simulations. The boxes enclose the 25th and 75th percentile, the horizontal center line denotes median values, and boxplot whiskers extend to the minimum and maximum values.

Fig. 4. Time series of bluegill, largemouth bass, and catfish biomass in four management scenarios; biomass is represented as relative to the management scenario with no insecticide, i.e. MS No pesticide. The insecticide exposure profile was provided by the Insecticide Root Zone Model (PRZM). MS 0 is the scenario without any management, MS 10 is a scenario with a 10× reduction in exposure, MS 25 is a scenario with a 25× reduction in exposure and MS No pesticide represents a scenario in which the insecticide was not used.

Fig. 5. Simulated Secchi depths (m) during the full recreational season from April 1st to October 31st, which is a total of 214 days for years 1970 to 1977, 31 d in 1969 and 183 d 1978, under different management scenarios (MS). MS 0 is the scenario without any management, MS 10 is a scenario with a 10× reduction in insecticide exposure, MS 25 is a scenario with a 25× reduction in exposure and MS No pesticide represents a scenario in which the insecticide was not used. Box plots represent values in one year of the simulation, with denoted median values, whereas box plot whiskers extend to the full range of values.

perturb the system in the following season (spring 1970) which resulted in more variability across management scenarios and years. Nevertheless, there was a clear impact of the insecticide. In the years 1971–1972, when simulated concentrations were higher than in other years (Fig. 4), Secchi depths for all insecticide-use scenarios were smaller than in other years. Across all simulation years, mean water clarity in the recreational season was 0.88 m (± 0.51 SD) in the no management scenario, 1.5 (± 0.8 SD) in the MS 10, 1.8 m (± 0.77 SD) in the MS 25, and 2.02 m (± 0.6 SD) in the scenario with no insecticide use.

3.2. Ecosystem services valuation

3.2.1. Abundance of game fish

Valuation of the ecosystem service of abundance of game fish for anglers estimated the marginal values of management scenarios considered here over the baseline (MS 0) to increase between \$300,000 and \$500,000 for bass and walleye (Fig. 6), with overlapping confidence intervals. As walleye had the same responses as largemouth bass, values for both species were increased in the MS 25 when compared to MS No pesticide. Bluegill did not increase in value, except in the MS No pesticide scenario, in which the value was increased by \$276,000. Catfish decreased in value for all scenarios presented here. Decreases ranged from \$500,000 to \$800,000 over the nine year simulation period.

3.2.2. Water suitability for swimming

We estimated a marginal change in water clarity value of \$0.21 m^{-1} household $^{-1}$ lake $^{-1}$ y $^{-1}$ based on (Egan et al., 2009). The number of reservoir visits per household increased from a median below 0.1 for MS 10 to a median of 0.18 as exposure to the insecticide decreased (Fig. 7). This increase in visits was associated with a higher willingness to pay on a per-household basis for increased water clarity (results not shown). When expanded to the number of households in Johnston County, we estimated a regional economic benefit realized by waders and swimmers of between \$6000 (MS 10) and \$15,000 (MS No pesticide) (Fig. 7). Furthermore, the variability in values declined as the level of insecticide decreased in the simulated lake.

4. Discussion

The goal of this study was to use an ecological model to quantify changes in the provisioning of ecosystem services associated with

Fig. 6. Change in value associated with the ecosystem service of recreational fishing, estimated by willingness to pay (WTP), on four species in different management scenarios. Error bars represent 95% confidence intervals around annual means. MS 10 is a scenario with a 10 $\times$ reduction in exposure, MS 25 is a scenario with a 25 $\times$ reduction in exposure and MS No pesticide represents a scenario in which the insecticide was not used. WTP is the willingness-to-pay for recreational fishing.

Fig. 7. Increased recreational use (left axis) and total value (right axis) across the county for Iowa swimmers. MS 10 is a scenario with a 10 $\times$ reduction in insecticide exposure, MS 25 is a scenario with a 25 $\times$ reduction in exposure and MS No pesticide represents a scenario in which the insecticide was not used. The boxes enclose the 25th and 75th percentile, the horizontal center line denotes median values, and box plot whiskers extend to the minimum and maximum values.

alternative management scenarios. We applied a well-established aquatic ecosystem model to quantify the impacts of a hypothetical insecticide on several ecosystem services provided by a generic reservoir lake. Our case study illustrates a modeling framework that can prove useful in evaluating management approaches and resolving tradeoffs in ecosystem services. Although the results are purely dependent on the assumptions and data for this hypothetical case study, they nonetheless show that the best management approach may depend on which services we aim to protect. We have shown that ecosystem services can respond to the presence of an insecticide differently and that careful consideration of service beneficiaries and their values needs to be incorporated into the risk assessment process if ecosystem service delivery is a protection goal.

4.1. Abundance of game fish

Hypothetical exposure to the insecticide affected fish species differently. Differences depended on the magnitude of direct effects, i.e. the species sensitivity to the chemical, and indirect effects, i.e. effects mediated through the food web. Both bluegills and their main prey (daphnids) were highly sensitive to the modeled insecticide (lowest toxicity endpoints, SI Table 1). Consequently, management scenarios that resulted in large insecticide runoff to the reservoir resulted in extirpation of both populations. However, at MS 10 and 25 daphnids recovered, but the bluegills did not. Being one of the main preys of largemouth bass, which had the highest biomass at MS 25, resulted in relatively low overall bluegill biomass for the majority of management scenarios. Largemouth bass and walleye experienced similar dynamics (data for walleye not shown because they are the same as bass). Both populations reached very low levels in scenarios with higher insecticide concentrations. However, biomass of both species was highest in a low-insecticide scenario, MS 25, suggesting that they benefitted from low concentrations of the modeled insecticide in the system. A closer inspection of the trophic matrix (SI Table 2) suggested that a potential cause could be increased detrital biomass which then impacted bass and walleye via the detrital food web. Detritivores, such as chironomids and *Tubifex*, represent the main food resource for largemouth bass juveniles. However, the prey base for walleye included mostly other fish species such as shad and especially buffalofish, which are relatively insensitive to the modeled insecticide and feeds largely on detritivores. So even though biomass increases of both species were driven by the

detrital food web, the effect on bass was direct, whereas increased resources for walleye were mediated by intermediary prey species.

On the other end of fish responses was the three-fold increase in catfish biomass in the baseline scenario which could not be explained merely by low sensitivity to the modeled insecticide. The trophic matrix details revealed that walleye substantially rely on catfish and buffalofish and that the insecticide-induced decline in walleye released juvenile catfish from predation; at MS 25 the high walleye biomass induced the biggest decline in catfish out of all management scenarios. Insecticide use also led to an increase in chironomid biomass which forms the base of the catfish diet and thus further increased catfish biomass. A combination of low sensitivity to the insecticide, diminished predation pressure and an increase in prey biomass resulted in overall positive impacts of the modeled insecticide for this species.

These differences in fish biomass dynamics translated into different economic benefits and losses among scenarios, which varied substantially across years. Variability in economic value was expressed as the difference across years attributed to differences in biomass output of AQUATOX. This difference was likely driven by simulated weather that influenced insecticide loading to the reservoir, e.g., increased rainfall leads to increased runoff from treated fields, and by temperature impacts on the simulated community. Year-to-year variability in number of trips or WTP was not accounted for, as these data were not available.

These results illustrate how tradeoffs among ecosystem services may influence management decisions. Because different results were observed for different species of fish, the decision to manage the use of the insecticide for the ecosystem service of angling will depend upon the favored species of fish. If beneficiaries value walleye and bass fishing above fishing for bluegill, any management that reduces insecticide exposure (from MS 10 to MS 100) will be sufficient for improving the ecosystem service of interest. On the other hand, if anglers prefer to fish for bluegill, then only no use of the insecticide in the watershed will be sufficient. Any management of the insecticide would result in economic losses if anglers prefer to fish for catfish.

4.2. Water clarity

We simulated the impacts of an insecticide on grazing zooplankton, which resulted in increased phytoplankton biomass and decreased water clarity in the reservoir. Our case study showed that waders and swimmers experienced a monotonic increase in this ecosystem service in response to reduced insecticide use. Water clarity, as measured by Secchi depth, varied substantially across years and simulated scenarios, possibly because phytoplankton biomass is driven by a multitude of factors (Boyce et al., 2010; Carpenter et al., 1998b). Water clarity is affected by ecosystem properties, such as fish community composition and the relative abundance of macrophytes versus algae. In real systems, other drivers also contribute to water clarity, such as suspended sediment (Davies-Colley and Smith, 2001), dissolved organic matter (Solomon et al., 2015) or water chemistry, such as presence of tannins (Stumm and Morgan, 1970). In our hypothetical shallow reservoir, water clarity was mostly driven by changes in food web dynamics, specifically the presence of zooplankton, which is common in shallow lakes (Jeppesen et al., 1999).

The increase in water clarity with reduced insecticide use described above was accompanied by a monotonic increase in value. A significant, linear relationship was reported between Secchi depth and distance traveled to visit lakes in Iowa and Minnesota, as determined by photo-visitation (Keeler et al., 2015). The relationship was significant for Iowa lakes alone, where mean Secchi depth was 1.1 m, but not for Minnesota lakes alone, which have a mean Secchi depth of 2.7 m. This may suggest that differences in clarity become less important as clarity improves, a finding that was not possible to consider in our case study. Furthermore, the public benefits more from paying to improve at least one lake to a higher level of clarity than to increase the clarity of all lakes by a smaller amount (Egan et al., 2009). This is, in part, because clarity

improvements smaller than 0.5 m are visually imperceptible (Smeltzer and Heiskary, 1990). In our study, changes in Secchi depth between scenarios with no insecticides and those in which different management strategies were implemented ranged from 0.7 (MS 0 to MS 10) to 1.1 m (MS 0 to MS No pesticide). This suggests that improvements would be visible to, and presumably valued by the public.

Here, we have demonstrated the implications for management of taking different beneficiary preferences into account. If walleye or largemouth bass are preferred over other fish, then reducing insecticide loading by a factor of 10 would markedly increase service delivery compared to the baseline (no management) scenario. At the same time, catfish would incur a modest reduction in biomass, and there would be a substantial increase in water clarity. In monetary terms, the MS 10 would yield a net benefit of ~\$670,000 which is the sum of the mean increased value of largemouth bass, walleye biomass, and bluegill and water clarity. If we were to add the losses associated with reduced catfish, then a net benefit of \$32,000 would be expected. For comparison, removing insecticide use from the region would yield a benefit of ~\$1,100,000; this is the sum of the mean increase in biomass of largemouth bass, walleye, and bluegill and increased water clarity. Subtracting the losses from reduced catfish biomass results in a net value of \$270,000 over the whole simulation period.

It is worth noting that we did not account for services derived from agriculture in the watershed surrounding this reservoir. Furthermore, we did not account for direct or indirect costs of different management scenarios on agriculture. We assumed that insecticide loading in the watershed could be reduced with different mitigation measures, such as reduced application rates and frequencies or use of buffer strips, or wetlands (Reichenberger et al., 2007); however, these mitigation measures may come at a cost to growers. For example, constructing wetlands may be costly whereas using the appropriate insecticide application nozzle size is less so (Reichenberger et al., 2007). In some cases, mitigation can also generate income for farmers. For example, three-stage buffers from which perennial grasses, willow and poplar are harvested for biomass energy (Jager and Efromson, 2018; Maringanti et al., 2011). In order to consider additional impacts of possible management options, it may be useful to include a quantitative analysis of the costs or benefits associated with actions that would serve to implement the possible management scenarios.

Furthermore, our hypothetical example was designed to illustrate the worst-case insecticide effects using available models and data expected to be available for an insecticide. The model we used to derive exposure concentrations is conservative in its choice of parameters and assumptions, yielding worst-case exposure concentrations. There are other factors that may impact pesticide loading, such as implementation of agricultural best management practices, use of lower rates (than allowed on the label) and a lower proportion of fields treated within the watershed (i.e., we assumed all of the agricultural acres in the watershed were treated). Analysis of water samples from reservoirs in the Northern Great Plains reveals that for the period of 2003–2005, the maximum detected concentration of the organophosphate chlorpyrifos was 0.02 µg/L (Donald et al., 2007). Observations that empirical concentrations are orders of magnitude lower than modeled estimates (mean simulated concentration was 5 µg/L), support the assumption that the baseline exposure (MS 0) modeled in this analysis was conservative. This suggests that risk assessments should take into account measured, and not exclusively modeled, exposures. Moreover, other consequences of agricultural practices were also omitted from this study. Nutrient run-off may cause substantial disruption to aquatic ecosystems, including algal blooms, hypoxic events or shifts in the whole food web (Carpenter et al., 1998a; Scheffer et al., 1993). Increased input of suspended inorganic solids has been demonstrated to adversely affect biomass and diversity of both plants and consumers in streams and experimental systems (Matthaei et al., 2010; Townsend et al., 2008). However, our aim was not to perform an actual risk assessment, which would need to take into account various other sources of stress,

but instead to provide an example of how provision of ecosystem services to different beneficiaries can be simulated under different insecticide management scenarios to facilitate decision-making in ecological risk assessment and management (Evans et al., 2013; Forbes et al., 2017). To clearly demonstrate this, we used a wide range of exposures that ensured a larger disruption to the ecosystem and possible ecosystem service trade-offs. Finally, it is also important to note that pesticides with other modes of action would likely result in different outcomes. Quantifying impacts on ecosystem services from exposure to herbicides, fungicides, or other insecticides, was beyond the aims of this study. However, if toxicity data exist, the methodology reported here could readily be applied to other classes of chemicals.

Our study clearly showed the importance of considering nonlinear ecosystem feedbacks when attempting to assess risk from chemicals and other stressors (De Laender and Janssen, 2013). The presence of some level of insecticide changed the modeled food-web dynamics in non-linear ways, resulting in increased catfish biomass in all scenarios, and walleye and largemouth bass in low insecticide scenarios (MS 25). It is highly unlikely that such responses would have been detected without the use of quantitative models that integrate relevant ecological information. Our study highlights one of the main advantages of using ecological models for risk assessment, namely the ability to generalize to meaningful levels of organization that matter to society, rather than individual-level toxicological sensitivity of a handful of species (Forbes and Galic, 2016; Forbes et al., 2017). The models also facilitate quantitative comparisons among alternative scenarios while explicitly accounting for different groups of beneficiaries and potential trade-offs among them. This approach has the potential to enhance the transparency and consistency of risk assessments by enlisting and representing different stakeholder communities, and may thereby improve environmental management decisions.
