Abstract

Variability in soil respiration at various spatial and temporal scales has been the focus of much research over the last decade aimed to improve our understanding and parameterization of physical and environmental controls on this flux. However, few studies have assessed the control of landscape position and groundwater table dynamics on the spatiotemporal variability of soil respiration. We investigated growing season soil respiration in a ~393 ha subalpine watershed in Montana across eight riparian–hillslope transitions that differed in slope, upslope accumulated area (UAA), aspect, and groundwater table dynamics. We collected daily-to-weekly measurements of soil water content (SWC), soil temperature, soil CO₂ concentrations, surface CO₂ efflux, and groundwater table depth, as well as soil C and N concentrations at 32 locations from June to August 2005. Instantaneous soil surface CO₂ efflux was not significantly different within or among riparian and hillslope zones at monthly timescales. However, cumulative integration of CO₂ efflux during the 83-day growing season showed that efflux in the wetter riparian zones was ~25% greater than in the adjacent drier hillslopes. Furthermore, greater cumulative growing season efflux occurred in areas with high UAA and gentle slopes, where groundwater tables were higher and more persistent. Our findings reveal the influence of landscape position and groundwater table dynamics on riparian *versus* hillslope soil CO₂ efflux and the importance of time integration for assessment of soil CO₂ dynamics, which is critical for landscape-scale simulation and modeling of soil CO₂ efflux in complex landscapes.

Keywords: soil respiration, CO₂, landscape, groundwater, riparian–hillslope, C:N ratios, topography, SWC

Introduction

Soil respiration constitutes the largest terrestrial flux of CO₂ to the atmosphere, contributing over an order of magnitude more CO₂ than anthropogenic sources (Raich *et al.*, 2002). Past research has examined the spatial variability of soil respiration across landscapes and has revealed important differences in this flux associated with spatial location. For example, significant differences in soil respiration have been found between north- and south-facing slopes in the northern hemisphere (Kang *et al.*, 2006), across wet and dry landscape positions (Davidson *et al.*, 1998; Pacific *et al.*, 2008, 2009; Riveros-Iregui *et al.*, 2008; Webster *et al.*, 2008), and as a result of the distribution, quantity, and quality of organic matter (Raymment and Jarvis, 2000; Epron *et al.*, 2004; Webster *et al.*, 2008). More recently, it has been demonstrated that at large scales (~km²), the spatial variability of soil respiration is organized by landscape morphology and structure (Riveros-Iregui and McGlynn, 2009), and that

this large spatial variability can even result in opposing responses of soil respiration to climatic forcing (Pacific *et al.*, 2009). While progress has been made in understanding the controls of soil respiration variability, one area that needs further investigation is the influence of groundwater table dynamics and landscape structure and attributes, which is the focus of this study.

It has been suggested that 70% of the western US carbon sink occurs at elevations above 750 m (Schimel *et al.*, 2002), and often in complex topography, which we define here as 5–45% slopes, combined topographic convergence and divergence, contrasting aspects, multiple landscape elements, variable groundwater dynamics, and heterogeneous land cover. Therefore, it is essential to understand and consider the role of landscape position and biophysical gradients as drivers of soil respiration in these montane settings.

It is well established that CO₂ in soil pore spaces is primarily the result of autotrophic (root) and heterotrophic (microbial) respiration. Soil CO₂ production is

generally controlled by soil temperature and soil water content (SWC) (Raich and Schlesinger, 1992; Fang and Moncrieff, 1999; Tang and Baldocchi, 2005), as well as the availability of soil organic matter (SOM) (Schoor and Trumbore, 2006; Scott-Denton *et al.*, 2006). Traditionally, it is accepted that increases in both soil temperature (Fang and Moncrieff, 2001; Yuste *et al.*, 2007; Xu and Wan, 2008) and SWC (Davidson *et al.*, 1998, 2000; Liu and Li, 2005; Risch and Frank, 2007) promote higher soil CO₂ production. However, soil respiration rates can quickly decline when soils are very wet (Happell and Chanton, 1993; Davidson *et al.*, 1998; Gullledge and Schimel, 2000) or very dry (Conant *et al.*, 1998; Welsch and Hornberger, 2004; Riveros-Iregui *et al.*, 2007, 2008). Increased soil CO₂ production has also been attributed to greater root exudation at times of high photosynthetic activity (Baldocchi *et al.*, 2006), which can stimulate soil heterotrophic activity.

The efflux of CO₂ from the soil to the atmosphere is the balance between soil CO₂ production and soil gas diffusivity (i.e. transport through the soil profile). An increase in SWC often leads to higher soil CO₂ production (Davidson *et al.*, 1998, 2000), but can simultaneously reduce soil gas transport (Millington, 1959; Washington *et al.*, 1994; Moldrup *et al.*, 2000, 2001). This production-transport relationship can result in short-term efflux equifinality (i.e. comparable outcomes with different combinations of the variables) across landscapes where SWC-mediated CO₂ production and transport are spatially variable (Pacific *et al.*, 2008). For example, Pacific *et al.* (2008) found that despite concentration gradients from the soil to the atmosphere that were nearly an order of magnitude higher in riparian *versus* hillslope zones, efflux was similar across short (daily) timescales. Their work suggested that surface CO₂ efflux in wet riparian soils was limited by low soil gas transport (despite high soil CO₂ concentrations), whereas efflux in dry hillslope soils was limited by low soil gas production (despite high soil gas diffusivity), resulting in similar efflux. McCarthy and Brown (2006) and Sotta *et al.* (2006) also found similar efflux across upland and low-land positions under significantly different SWC.

Significant differences in the drivers of soil respiration can exist as a function of landscape position. For example, higher SWC and higher and more persistent groundwater tables are often observed in convergent (Dunne and Black, 1970; Anderson and Burt, 1978; McGlynn and Seibert, 2003), depressional (Parkin *et al.*, 2005), lower slope positions (Sotta *et al.*, 2006; Pacific *et al.*, 2008; Xu and Wan, 2008), and locations with high upslope accumulated area (UAA, a measure of the area of land draining to a particular location) (Jencso *et al.*, 2009; Pacific *et al.*, 2010). This variability in SWC can in turn affect other soil respiration-driving variables, such as the abundance of SOM (Ostendorf, 1996; Sjogersten *et al.*, 2006) and magnitude of soil gas diffusivity (Millington, 1959; Moldrup *et al.*, 2001; Schwendenmann *et al.*, 2003; Sotta *et al.*, 2007). Aspect can be a strong control on soil temperature, with higher soil temperatures generally found on south-facing slopes in the northern hemi-

sphere (Kang *et al.*, 2006). Spatial variability in vegetation can also influence soil respiration due to differences in root respiration and the quantity and quality of detritus (Raich and Tufekcioglu, 2000). These biophysical gradients across landscape positions can lead to strong spatial heterogeneity in soil respiration.

Riparian and hillslope zones are two dominant landscape elements in headwater catchments and generally have distinct SWC and groundwater table regimes, leading to differences in soil and vegetation characteristics (Hill, 1996; McGlynn and Seibert, 2003). The riparian zone can be defined as the near-stream area between the hillslope and stream channel (Seibert and McGlynn, 2005), and is often characterized by hydromorphic soils (Phillips *et al.*, 2001; Cosanday *et al.*, 2003; Mourier *et al.*, 2008), high SOM (McGlynn and McDonnell, 2003; Hill and Cardaci, 2004; Hill *et al.*, 2004; Gurwick *et al.*, 2008), and a marked decrease in slope from the adjacent hillslope zone over very short distances (~1 m) (Merot *et al.*, 1995; Jencso *et al.*, 2009). The transition between riparian and hillslope zones offers unique opportunities to investigate the role of landscape position and biophysical variables on soil respiration due to strong gradients of SWC, soil temperature, soil gas diffusivity and SOM, and variable groundwater dynamics, all of which arise over short spatial scales. We present measurements of growing season (June–August) surface CO₂ efflux, soil CO₂ concentrations, SWC, soil temperature, groundwater dynamics, and soil C and N concentrations at 32 positions along eight riparian-hillslope transitions (four locations per transect) in a complex subalpine watershed in the northern Rocky Mountains. We examine how short-scale (~m) gradients in biophysical and hydrological controls influence the generation and flux of soil CO₂ in a topographically complex watershed. We seek to address the following questions:

1. How do landscape positions and attributes (e.g. slope, UAA, and aspect) relate to spatial and temporal patterns of groundwater depth, SWC, and soil respiration across riparian-hillslope transitions?
2. How does surface CO₂ efflux differ between two hydrologically distinct landscape positions: riparian (wet) and hillslope (dry) areas?
3. How can landscape metrics be used to explain dynamics between surface CO₂ efflux and SWC or soil temperature across multiple riparian and hillslope positions?

Materials and Methods

Site description

This research was conducted in the United States Forest Service Tenderfoot Creek Experimental Forest (TCEF; latitude 46°55'N, longitude 110°52'W) within the upper-Stringer Creek Watershed (~393 ha). The TCEF is located in the Little Belt Mountains within the Lewis and Clark National Forest of central Montana (Figure 1), and

Figure 1. LIDAR (ALSM) topographic image (resolution < 1 m for bare earth and vegetation) of the upper-Stringer Creek Watershed (393 ha) within the TCEF (Lewis and Clark National Forest), Montana (latitude 46°55'N, longitude 110°52'W). Transect and soil respiration measurement locations are shown.

is characteristic of subalpine watersheds in the northern Rocky Mountains (wide range of slope, aspect, and topographic convergence/divergence). Elevation ranges from 1840 to 2421 m, with a mean of 2205 m.

The mean annual temperature is 0 °C, with mean daily temperatures ranging from – 8.4 °C in December to 12.8 °C in July (Farnes *et al.*, 1995). Annual precipitation averages 880 mm, with ~70% falling as snow from November to May, with typical snow depths of 1–2 m. We defined the growing season as mid-June to August using an air temperature threshold. This was the approximate time period during which average minimum daily temperatures remained above freezing, based on the 10-year data record from the Natural Resource and Conservation Service Onion Park SNOTEL site located ~2 km from the transect locations and at approximately the same elevation.

Lodgepole pine (*Pinus contorta*) is the dominant overstory vegetation (Farnes *et al.*, 1995); subalpine fir (*Abies lasiocarpa*), Douglas-fir (*Pseudotsuga menziesii*), Englemann spruce (*Picea engelmannii*), and whitebark pine (*Pinus albicaulis*) are also present. Trees are present on the hillslopes along each transect and are generally not found in the riparian areas. Grouse whortleberry (*Vaccinium scoparium*) is the dominant understory species in the uplands, whereas riparian vegetation is mainly composed of bluejoint reedgrass (*Calamagrostis canadensis*) (Mincemoyer and Birdsall, 2006). In general, west-aspect hillslopes often have a denser canopy cover and later snowmelt in this catchment. The geology is characterized by granite gneiss, shales, quartz porphyry, and quartzite (Farnes *et al.*, 1995), and the most extensive soil types are loamy skeletal, mixed Typic Cryochrepts, and clayey mixed Aquic Cryoboralfs (Holdorf, 1981).

Landscape characterization

Eight transects (~50 m long) were identified within the upper-Stringer Creek Watershed (Figure 1). Each transect originated at Stringer Creek, which flows north to

south, and extended up the fall line through the riparian zones and adjacent hillslopes. The transects were labeled T1 through T8, and located in east–west pairs (odd = west, even = east) along four stream reaches of Stringer Creek. T1 and T2 were the northern-most (upstream) transects, and T7 and T8 the southern-most (downstream) transects. The riparian–hillslope transition was defined by a break in slope, higher and more sustained groundwater tables in the riparian zones (often leading to saturated conditions), difference in soil depth (0.5–1 m in the hillslopes and 1–2 m in the riparian zones), change in soil properties (more organic soils in the riparian zones and more mineral soils in the hillslopes) (Seibert and McGlynn, 2007; Jencso *et al.*, 2009), and transition in dominant vegetation (bluejoint reedgrass in the riparian zones and grouse whortleberry in the hillslopes) (Mincemoyer and Birdsall, 2006). Four instrumentation nests were installed along each transect, two each in the riparian and hillslope zones. The nests were labeled 1–4, with 1 being furthest up the hillslope and 4 closest to Stringer Creek. Some nests were reclassified as either riparian or hillslope once data collection began due to groundwater table dynamics (T3–2 as riparian and T2–3, T5–3, and T7–3 as hillslope) (Seibert and McGlynn, 2007).

Terrain analysis

An airborne laser swath mapping (ALSM) [commonly known as light detection and ranging (LIDAR)] 3-m digital elevation model (DEM) was used to calculate UAA (calculated at the instrument nest closest to the stream on each transect, e.g. T1–4, T2–4) and slope (average slope along the fall line from the highest to lowest hillslope location, e.g. T1–1 to T1–2) along each transect (Seibert and McGlynn, 2007). Riparian zone width was calculated using a Global Positioning System (GPS) survey (Trimble GPS 5700 receiver) (Jencso *et al.*, 2009). The topographic wetness index (TWI), which can be interpreted as a relative wetness index, indicated landscape

position wetness propensity with the following equation (Beven and Kirkby, 1979):

$$TWI = \ln \left(\frac{a}{\tan \beta} \right) \quad (1)$$

where a is UAA, and β is the local slope.

Environmental measurements

Along each transect, environmental measurements were collected every 1–5 days from June 9 to August 31, 2005. Both volumetric SWC ($\text{cm}^3 \text{H}_2\text{O}/\text{cm}^3$ soil, integrated over the top 20 cm of soil; Hydrosense portable SWC meter, Campbell Scientific Inc., Utah, USA) and soil temperature (12-cm soil thermometer, Reotemp Instrument Corporation, San Diego, California, USA; measurement range of -20 to 120°C , temperature measured at 10 cm depth) were manually collected within a 1 m^2 measurement area at each nest location. SWC was measured three times to capture the variability of SWC at each nest, and the mean of the three measurements was used for data analysis.

The Hydrosense portable SWC meter was calibrated using a time domain reflectometry (TDR) system developed following Robinson *et al.* (2003). The TDR sensor was tested in the laboratory by comparing TDR and gravimetric measurements over a wide range of SWC (data not shown). Approximately 300 SWC measurements were collected in the field with both instruments. Measurements were comparable in the mineral upland soil ($r^2 = 0.99$), but SWC was overestimated by the Hydrosense in the organic riparian soil. The following equation was therefore used to adjust Hydrosense SWC measurements in the organic riparian soil (Pacific *et al.*, 2008):

$$\text{SWC} = (0.7704 \times \text{Hydrosense measurement}) + 0.8774 \quad (r^2 = 0.986) \quad (2)$$

Soil carbon and nitrogen concentrations

At each nest location, two 10-cm soil cores were collected, with the center of each core at the depth of interest (20 and 50 cm) with a hand auger (7.5 cm diameter, 10 cm height) from July 26 to 30, 2005. The soil cores were dried, homogenized, sieved (60-mesh, $250 \mu\text{m}$ screen), ground into a fine powder using a mortar and pestle, and weighed and analyzed for total C and N concentrations using a C and N analyzer (LECO TruSpec CN, Leco Corporation, St. Joseph, Michigan, USA). Molar soil C:N ratios were then calculated.

Soil bulk density and root density

Bulk density of the upper 5 cm of soil was measured with a 5-cm diameter bulk density sampler. Soil root density was measured from soil samples collected from the upper 20 cm of soil using a hand auger (5 cm diameter). The samples were dried, and the roots were manually separated and weighed in the laboratory.

Hydrological measurements

Groundwater wells (screened from the completion depth of 0.5–2 m to within 0.2 m of the ground surface) were installed at riparian and lower hillslope nests (i.e. 4, 3, and 2) along each transect. Groundwater levels were recorded every 30 min using capacitance rods (± 1 mm resolution, Tru Track, Inc., New Zealand). Installation of 24 capacitance rods occurred from the beginning of June until the middle of July (due to limited availability from the manufacturer), and manual measurements of groundwater depth were collected to quantify groundwater dynamics over the entire measurement period. Manual measurements were collected with an electric water level meter every 5–7 days from mid-June to mid-July (time period following snowmelt when groundwater dynamics were highly variable), then every 2–4 weeks until the end of August.

Soil CO_2 concentration measurements

Following the methods described by Andrews and Schlesinger (2001) and Welsch and Hornberger (2004), soil air gas wells [15-cm section of 5.25-cm (inside diameter) polyvinyl chloride (PVC)] were installed at completion depths of 20 and 50 cm at each nest (total of two gas wells per nest). The top of each gas well was capped with a size 11 rubber stopper through which passed two pieces of PVC tubing (4.8 mm inside diameter Nalgene 180 clear PVC, Nalge Nunc International, Rochester, New York, USA) that extended above the ground surface. To ensure that no gas escaped while measurements were not being collected, the tubing was joined with plastic connectors (6–8 mm high density polyethylene (HDPE) FisherBrand tubing connectors, Fisher Scientific, USA).

Soil air CO_2 concentrations were measured by attaching the two sections of gas well tubing to a portable infrared gas analyzer (IRGA) [model EGM-3, accurate to within 1% of calibrated range (0–50,000 ppm); PP Systems, Massachusetts, USA] or [model GM70 with M170 pump and GMP 221 CO_2 probe, accurate to within 1% of calibrated range (0–50 000 ppm); Vaisala, Finland], as performed by Pacific *et al.* (2008). Two IRGAs were available in case one needed to be recalibrated, and measurements were routinely compared in the field to ensure validity. The air from the gas well was circulated through the IRGA and returned to the gas well, creating a closed loop and minimizing pressure changes during sampling. Both instruments were allowed a 30-min warm-up time (per the manufacturer's recommendations), and after which remained on for the duration of measurements. CO_2 concentration measurements required 2–5 min (recirculation time) before stabilized values were recorded. Recirculation time did not affect soil CO_2 concentrations in our experimental design or similar designs (Andrews and Schlesinger, 2001; Welsch and Hornberger, 2004; Pacific *et al.*, 2008). Soil CO_2 concentration measurements were internally corrected for air temperature and pressure with the EGM-3, and com-

compensated for air temperature and pressure for the GMP 221 following recommendations by the manufacturer (www.vaisala.com).

Surface CO₂ efflux measurements

A 0.5 m² surface CO₂ efflux plot, roped off to minimize soil trampling, was selected at each nest location. To minimize the effect of above-ground autotrophic respiration inside the chamber, vegetation within the efflux plot was clipped approximately once per week after a round of measurements was collected. Plant roots were left intact to minimize disturbance to below-ground root respiration. A soil respiration chamber [SRC-1 chamber with a footprint of 314.2 cm², accurate to within 1% of calibrated range (0–9.99 g CO₂ m⁻² hr⁻¹)] in conjunction with an IRGA [EGM-4, accurate to within 1% of calibrated range (0–2000 ppm); PP Systems, Massachusetts, USA] was used to measure surface CO₂ efflux. Three measurements were collected per nest location and averaged for data analysis. The chamber was flushed with ambient air for 15 s and then inserted 3 cm into the soil (size of attached collar) before each measurement began. We estimated cumulative efflux from June 9 to August 31, 2005 by linearly interpolating between measurements collected every 2–7 days. Previously demonstrated for this site (Riveros-Iregui *et al.*, 2008; Riveros-Iregui and McGlynn, 2009), this was a robust approach for comparison of efflux measurements across multiple locations over extended periods of time, and that sampling frequency did not bias cumulative efflux estimates.

Soil gas diffusivity

We inversely calculated “effective” soil gas diffusivity for the upper 20 cm of the soil profile (which provided an estimate of D in the following equation) using Fick’s Law and measured values of surface CO₂ efflux, 20 cm soil CO₂ concentrations, and an assumed atmospheric CO₂ concentrations of 400 ppm:

$$\text{Flux} = -D \frac{\partial C}{\partial z} \quad (3)$$

where D is the diffusivity (m² s⁻¹), C the CO₂ concentration (ppm), and z the depth (m). A recent study demonstrated that the assumed values do not compromise calculation of soil CO₂ efflux, as the diel variability of soil CO₂ concentration in depth is much greater than the diel variability of CO₂ above the soil surface given the atmospheric buffer (Riveros-Iregui *et al.*, 2008).

Statistical analyses

Analysis of variance (ANOVA) ($\alpha = 0.05$) was used to test for differences in soil CO₂ concentrations, soil temperature, SWC, soil gas diffusivity, soil C and N concentrations and respective molar soil C:N ratios, and surface CO₂ efflux both within transects (riparian versus hillslope) and among the eight transects (riparian versus riparian and hillslope versus hillslope). For comparisons among the eight transects, n ranged from three to eight

due to reclassification of some nests as either riparian or hillslope. Separate analyses were performed each month due to the temporal dynamics at this research site (with the exception of soil C and N concentrations and respective C:N ratios, as measurements were collected only once). For within-transect analyses, n was higher on T1–4 (ranging from 52 in June to 80 in July on T1–4 versus 24 in August to 44 in June on T5–8, as these transects had a higher sampling frequency (to increase temporal resolution)). For comparisons among the 8 transects, n ranged from 24 for T7 versus T8 in June to 80 for T1 versus T2 in July. Three measurements of SWC and surface CO₂ efflux were collected at each nest location on all sampling days and averaged for data analysis. To test the validity of the ANOVA approach and test for autocorrelation problems, we performed autocorrelation tests, which showed that our measurements had little to no temporal dependence over the monthly timescales used for the ANOVA analysis. Regression analysis was performed to assess the strength of the relationship between surface CO₂ efflux and SWC or soil temperature. Note that T1–2 efflux was unusually high and excluded from statistical analyses (except as presented in Figure 4).

Results

Landscape analysis

Landscape characterization results are summarized in Table I. UAA ranged from 1023 m² on T6 to 14,783 m² on T4, with the lowest values on downstream transects. The slope of the hillslopes generally increased moving downstream, ranging from 13.6% on T2 to 42.5% on T8. Riparian zone width ranged from 21.0 m on T3 to 4.7 m on T7, and was typically wider on upstream transects. TWI was in general highest on upstream transects and ranged from 8.0 on T8 to 11.5 on T3.

Table I. Landscape characterization of UAA, riparian zone width, predominate slope of hillslope, TWI, and median depth of groundwater (in the riparian zone) on each transect

Transect	UAA (m ²)	Riparian width (m)	Hillslope slope (%)	TWI	Depth to GW (med) (cm)
1	2249	12.7	18.1	9.4	14.5
2	1804	11.8	13.6	9.5	11
3	14,304	21.0	14.6	11.5	24
4	14,783	8.3	30.0	10.8	35
5	14,304	11.7	24.0	11.0	40
6	1023	6.5	21.4	8.5	47.5
7	1373	4.7	41.7	8.0	> 100
8	1755	9.9	42.5	8.3	49

UAA and slope were calculated using 3-m DEMs (Seibert and McGlynn, 2007). Transects 1 and 2 (east-west pair) are located furthest upstream, whereas Transects 7 and 8 (east-west pair) are located furthest downstream. On T7, no groundwater table development was observed above the well completion depth of 100 cm.

Soil carbon and nitrogen concentrations and molar C:N ratios

In the riparian zones, the mean and standard deviation of soil C concentrations were 2.3 and 1.1% at 20 cm and 1.8 and 0.9%, respectively, at 50 cm. In the hillslopes, soil C concentrations had a mean and standard deviation of 2.7 and 1.8% at 20 cm and 1.3 and 0.7%, respectively, at 50 cm. The mean and standard deviation of riparian zone soil N concentrations were 18 and 0.09%, respectively, at 20 cm, and 10 and 0.05% at 50 cm. Hillslope soil N concentrations had a mean and standard deviation of 0.12 and 0.06% at 20 cm, and 0.06 and 0.05%, respectively, at 50 cm.

There were differences in riparian *versus* hillslope molar soil C:N ratios within transects, with higher ratios in the hillslopes on T1, T3, and T4 at 20 cm, and on T3 and T4 at 50 cm (Figure 2). Overall, riparian molar soil C:N ratios had a mean and standard deviation of 14.1:1 and 2.6:1, respectively, at 20 cm, and 18:1 and 3.5:1 at 50 cm. In the hillslopes, the mean and standard deviation of molar soil C:N ratios were 30.6:1 and 10.1:1, respectively, at 20 cm, and 32.3:1 and 13.9:1 at 50 cm. There was also a general trend of decreasing molar soil C:N ratios from hillslope to riparian zones along each transect (Figure 2). Few differences in 20- and 50-cm molar soil C:N ratios were observed when comparing hillslope zones among the eight transects. However, there were often differences between the riparian zones of each transect. T2, T4, and T7 had higher, and T3, T6, and T8 lower riparian molar C:N ratios than other transects (Figure 2).

Soil bulk density and root density

In the riparian zones, soil bulk density had a mean and standard deviation of 0.962 and 0.046 g cm⁻³, respectively, compared with 0.911 and 0.076 g cm⁻³ in the hillslopes. Riparian zone soil root density had a mean and standard deviation of 11.5 and 2.5 g root kg⁻¹ soil, respectively, compared to 9.6 and 4.2 g root kg⁻¹ soil in the hillslopes. These differences in riparian and hillslope soil bulk density and root density were not significant.

Soil temperature

Soil temperature was not significantly different between riparian and hillslope zones within each transect (with the exception of localized differences on T3, T4, and T8 during June and July) (Table II, Figures 3–5). There were, however, significant differences in both riparian and hillslope zones between the eight transects (Figure 6). Colder soil temperatures were found during June and July on transects with a west aspect (even numbered transects), where snow was observed up to 3 weeks later than transects with an east aspect (particularly in the hillslopes). The number of significant differences in soil temperature among the eight transects decreased from June to August (Figure 6).

Soil water content

SWC (integrated over top 20 cm) was significantly higher in the riparian zones within each transect during

Figure 2. Bar graphs of soil C:N ratios in hillslope (black) and riparian (grey) zones along each transect at (A) 20 cm and (B) 50 cm. Note that a very high value was observed at T8-1 at 50 cm (123:1), and the value is written instead of plotted so as not to affect the bar graph scale.

the entire period of this study (Table II; Figures 3, 4, and 7). There were also significant differences when comparing both riparian and hillslope zones between the eight transects (Figure 8), with higher SWC generally measured on upstream transects (i.e. T1–4 versus T5–8). A general downstream decrease in SWC was observed, with a more pronounced trend in the riparian zones (Figure 3).

Groundwater depth

In the riparian zones on each transect, the depth of the groundwater table was generally within 20 cm of the ground surface at all wells at the beginning of June. The groundwater table then gradually declined at all locations throughout the measurement period. Hillslope groundwater table development was not observed on any transect over the course of this study; however, transient hillslope groundwater tables have been observed on some transects during peak snowmelt (Jencso *et al.*, 2010). Higher and more persistent riparian groundwater levels were often observed on upstream transects, where UAA is large, hillslopes are gentle, and TWI is high (Table I). The median depth of groundwater in the riparian zones on upstream transects over the study period ranged from 11 to 35 cm below the ground surface, and from 40 to > 100 cm below the ground surface on downstream transects (Table I).

Real-time groundwater table dynamics from the T1-4 and T6-4 measurement locations are presented in Figure 9 to highlight contrasting water table and surface CO₂ efflux dynamics between areas with large differences in UAA, slope, and TWI. At T1-4 (upstream transect, high TWI), the groundwater table was at the ground surface (saturation) at the beginning of June.

Saturation persisted until the beginning of July, and then the groundwater table gradually declined to 10 cm below the ground surface by the end of August, with a median depth of 5.1 cm over the measurement period. In contrast, at T6-4 (downstream transect, low TWI), the groundwater table was 10 cm below the ground surface at the beginning of June, but quickly declined to 30 cm by the end of June. The groundwater table then gradually declined for the remainder of the study period, reaching a maximum depth of 42 cm below the ground surface by the end of August. Median depth of the groundwater table over the course of this study at T6-4 was 33.6 cm below the ground surface.

Soil CO₂ concentrations

There were significant differences between riparian and hillslope soil CO₂ concentrations within each transect (Table II). Higher concentrations were generally measured at 20 cm in the riparian zones, whereas at 50 cm, higher concentrations were found in the hillslopes (Figure 3). There were also significant differences in soil CO₂ concentrations among the eight transects in both riparian and hillslope zones (Figures 3 and 8). At 20 cm, soil CO₂ concentrations in the riparian zone along T8 were always lower than other transects (with a few exceptions in August), and higher concentrations were often observed on T1. In the hillslopes, there were significant differences in 20 cm soil CO₂ concentrations among many transects in June, with fewer differences observed during July and August (Figure 8). Many 50 cm riparian zone soil CO₂ gas wells remained saturated by groundwater over the course of this study, and soil CO₂ concentrations could not be measured at these locations (denoted by flat lines in Figure 3D). Soil CO₂ concentrations at 50 cm could therefore not be compared among many transects (indicated by dashed lines in Figure 8). In general, there was a downstream decrease in soil CO₂ concentrations in the riparian and hillslope zones at both 20 and 50 cm (Figure 3). The downstream decrease of soil CO₂ concentration magnitude and variability was much more pronounced in the riparian zones, particularly at 20 cm.

Surface CO₂ efflux

In general, monthly averaged soil surface CO₂ efflux was not significantly different between riparian and hillslope zones within each transect based on ANOVA analysis (Table II). With the exception of T1, similar ranges and median values were observed in riparian and hillslope zones within each transect when grouping all data from June to August (Figure 3). Note that T1-2 efflux was unusually high and excluded from statistical analyses and is not presented in other figures. Differences in median efflux between riparian and hillslope zones within each transect were generally less than 0.1 g CO₂ m⁻² hr⁻¹, and similar minimum and maximum values were observed (Figure 3). However, significantly higher riparian zone efflux ($p < 0.01$) (25% higher in the riparian zones) became apparent when examining median cumulative efflux across all transects during the

growing season, which we define here as the 83-day period between June 9 and August 31. Riparian cumulative efflux ranged from 649 to 1918 g CO₂ m⁻² during the growing season, with a mean and standard deviation of 1012 and 354 g CO₂ m⁻² during the growing season, respectively (Figure 10). In contrast, hillslope cumulative efflux ranged from 432 to 1246 g CO₂ m⁻² during the growing season (excluding T1-2, which had a cumulative efflux of 1774 g CO₂ m⁻² during the growing season), with a mean and standard deviation of 809 and 222 g CO₂ m⁻² during the growing season, respectively (Figure 10). At T1-4 and T6-4, shown in Figure 9, cumulative growing season efflux was 1918 and 1025 g CO₂ m⁻² during the 83-day growing season, respectively.

Significant differences in monthly efflux among the eight transects were observed in both riparian and hillslope zones during June, July, and August (Figure 8). Median cumulative efflux during the growing season decreased with distance from channel head and ranged from 1160 g CO₂ m⁻² during the growing season on T1/T2 (200 m from channel head) to 810 g CO₂ m⁻² during the growing season on T7/T8 (1400 m from channel head) (Figure 10).

Figure 5. Bivariate plots of soil temperature and surface CO_2 efflux at riparian and hillslope zones along each transect, collected from June 9 to August 31, 2005. Solid line denotes linear regression, and p -values are provided for at $\alpha = 0.05$. Dark boxes indicate a statistically significant relationship.

There was no consistent relationship between surface CO_2 efflux and growing season soil temperature or SWC across all transects (Figure 4). Although statisti-

cally significant ($p < 0.01$) in both riparian and hillslope zones when all data were grouped together (Figure 4), these relationships showed low explanatory power (low r^2 values). Furthermore, when T1-2 was excluded from data analysis (Figure 4), the relationships became weaker, and in the case of hillslope efflux *versus* SWC, they were not significant (Figure 4C). When examining the data by individual transects, there were often significant relationships between surface CO_2 efflux and soil temperature, particularly in the riparian zones (Figure 5). However, the relationships were weak, and one relationship did not hold across all transects. Few significant relationships were found between efflux and SWC in both the riparian and hillslope zones across each transect (Figure 7).

Soil gas diffusivity

Significant differences between riparian and hillslope soil gas diffusivity were found within nearly all transects during both June and July (Table II), with higher diffusivity rates in the hillslopes along all transects (Figure 3). Riparian zone soil gas diffusivity varied significantly among most transects, whereas few differences were found among hillslopes (Figure 6).

Discussion

How do landscape positions and attributes (e.g. slope, UAA, and aspect) relate to spatial and temporal patterns of groundwater depth, SWC, and soil respiration across riparian-hillslope transitions?

Our results indicate that soil respiration varied across riparian and hillslope zones in the upper-Stringer Creek Watershed, which was potentially influenced by differences in landscape position and attributes, and associated spatial patterns of groundwater dynamics and soil wetness status. Consistent with prior observations at this site (Riveros-Iregui and McGlynn, 2009), we found that cumulative growing season soil respiration in grassy riparian zones was significantly higher than in the forested hillslopes, allowing for first-order discretization of the landscape into riparian meadows and upland forests. However, our results suggest that even within riparian areas, cumulative surface CO_2 efflux across the growing season was also landscape-controlled, with generally higher soil respiration on upstream transects (near the stream headwaters, Figure 11) and decreasing in the downstream direction. This was perhaps the result of higher upstream SWC and differences in riparian area width, UAA, slope, and groundwater table dynamics.

The relationship between slope, UAA, and SWC can be described by the TWI (Beven and Kirkby, 1979; Equation 1), which suggests that the wettest landscape positions will occur in areas with large UAA and gentle slopes (which therefore have high TWI values) (Bonell, 1998). This relationship was applicable in the upper-Stringer Creek Watershed, where higher SWC (Figure 7) and more persistent groundwater table development (average depth often less than 25 cm below the ground

Figure 6. ANOVA statistics ($\alpha = 0.05$) for transect-versus-transect comparisons of riparian and hillslope soil temperature, water content, and gas diffusivity during (A) June, (B) July, and (C) August, 2005. Shaded boxes indicate significant differences. n ranged from 24 for T7 versus T8 in June to 80 for T1 versus T2 in July.

surface over the course of the study) was observed on upstream transects, which are characterized by high UAA and gentle slopes (Table I). For example, T3 has high UAA and a very gentle slope, which resulted in a high TWI (11.5, Table I) and suggested that wetness status would be high (Beven and Kirkby, 1979; Bonell, 1998). This premise held true as SWC was high (Figure 7) and the groundwater table remained relatively close to the ground surface in the riparian zone on T3 (median depth of 24 cm below the ground surface). In contrast to upstream transects, UAA and the TWI were much lower and slopes much steeper on downstream transects (Table I). For example, UAA is small and slopes are steep on T7, and this resulted in much lower TWI (8.0) and SWC (Figure 3). At this location, the groundwater table never developed above the well completion depth of 100 cm. Based on our understanding of the relationships between soil wetness status, CO_2 efflux, and the TWI, higher efflux was expected along T3, where wetness status was higher, as increased SWC generally promotes higher rates of soil respiration (Davidson *et al.*, 1998, 2000; Liu and Li, 2005; Risch and Frank, 2007). Cumulative efflux was $1193 \text{ g CO}_2 \text{ m}^{-2}$ during the growing season on T3 (wet), while only $960 \text{ g CO}_2 \text{ m}^{-2}$ during the growing season on T7 (dry), confirming expectations based on topographic analysis and observations made across the entire forest (Riveros-Iregui and McGlynn, 2009). Thus, the concept of the TWI shows promise as an indicator of soil respiration across complex landscapes and is useful for interpretation of surface CO_2 efflux in a landscape context.

The downstream decrease in cumulative growing season efflux may have been in part the result of catchment morphology, which became narrower downstream and may be specific to the Stringer Creek Watershed. This morphology resulted in a downstream decrease in UAA and increase in slope (Table I), and lower SWC and groundwater table depth were observed downstream, which likely influenced the downstream decrease in efflux. However, catchments with different morphology may observe a different trend, and care should be taken when extrapolating the results of this study to catchments with different landscape structure.

The influence of catchment morphology on groundwater table dynamics and soil respiration was also evident when comparing sites at contrasting locations. Soil CO_2 efflux and groundwater dynamics at T1–4 (upstream, TWI = 9.4) and T6–4 (downstream, TWI = 8.5; Table I) are shown in Figure 9. At the beginning of June, the groundwater table was at or near the ground surface at both locations. However, the groundwater table was more persistent at T1–4, where soils remained saturated until the beginning of July, after which the groundwater table remained within 10 cm of the ground surface for the remainder of the measurement period (Figure 9). At this location, median SWC was 63% across the course of this study, confirming expectations of high wetness status in an area with relatively high UAA and gentle slopes (Table I). In contrast, the groundwater table quickly declined to 30 cm below the ground surface by the beginning of July at T6–4, and continued to decrease over the rest of the measurement period (Figure 9).

Figure 7. Bivariate plots of SWC and surface CO_2 efflux at riparian and hillslope zones along each transect, collected from June 9 to August 31, 2005. Solid lines denote linear regression, and p -values are provided for at $\alpha = 0.05$. Dark boxes indicate a statistically significant relationship.

At T6-4, UAA was less than half than that at T1-4, the slope was steeper (which resulted in a lower TWI than at T1-4), and SWC was lower (median of 53%). As expected, cumulative efflux was much higher at T1-4 ($1918 \text{ g CO}_2 \text{ m}^{-2}$ during the growing season) compared to only $1025 \text{ g CO}_2 \text{ m}^{-2}$ during the growing season at T6-4). This contrast in efflux between areas with large differences in landscape structure highlights the need to examine catchment morphology and resulting groundwater table dynamics and soil wetness status when ex-

amining soil respiration in complex landscapes.

The impact of variable SWC across the landscape on soil respiration is also apparent when examining soil gas diffusivity. In contrast to SWC, soil gas diffusivity increased downstream, but only in the riparian zones (Figures 3 and 6). We infer that significant differences in only riparian zone soil gas diffusivity were the result of a wider range of riparian SWC across the study period (35–85% in the riparian zones versus 10–40% in the hillslopes; Figure 3), as even small changes in SWC can significantly impact soil gas transport (Millington, 1959; Washington *et al.*, 1994; Moldrup *et al.*, 2000, 2001). This relationship between soil gas transport and SWC is supported by Risk *et al.* (2002), who observed differences in soil gas diffusivity of up to a factor of 10^4 across a similar range of riparian SWC observed in the Stringer Creek Watershed. Thus, the large variability in riparian (but not hillslope) SWC and soil gas diffusivity was potentially controlled by groundwater table dynamics. Groundwater table development was not observed above the well completion depths of 1–2 m in the hillslopes, and SWC never exceeded 40% and varied by only 30% across all transects. This small range in hillslope SWC resulted in less significant differences in soil gas diffusivity between hillslopes. In contrast, the groundwater table was at or near the ground surface at many riparian wells at the beginning of June, but declined by 20–80 cm by the end of August. This wider range in riparian groundwater table depth over the course of this study explains the wider range of riparian SWC and significant differences in riparian soil gas diffusivity between transects. It is possible that in the upper-Stringer Creek Watershed, a shift from wet to dry soil wetness status is necessary for significant differences in soil gas diffusivity to occur. In the hillslopes, SWC was already low at the beginning of June (maximum of 40%), and this “wet-dry” shift never occurred. In contrast, the SWC in the riparian zones was often over 60% at the beginning of June, but decreased to ~40% at many locations by the end of August. A strong “wet-dry” shift occurred at many riparian locations, which resulted in large differences in SWC, and therefore soil gas diffusivity among riparian zones.

Aspect (east versus west) generally did not impact growing season soil respiration within or among riparian and hillslope zones in the upper-Stringer Creek Watershed (Figure 3). There were significant differences in soil temperature between transects (Figure 6); however, these occurred early in the growing season as a result of differences in snowpack persistence as well as the influence of the high specific heat of water in saturated areas (Pacific *et al.*, 2008). Indeed, as all landscape positions became snowfree and SWC declined in many saturated areas, variability in soil temperature between east and west aspects was no longer statistically different (Figure 6). However, our results contrast with those of other studies of soil respiration in complex terrain. Kang *et al.* (2006) found higher soil temperatures on south- versus north-facing slopes in response to greater differences in incoming solar radiation between north and south aspects,

Figure 8. Analysis of variance statistics ($\alpha = 0.05$) for transect-versus-transect comparisons of riparian and hillslope soil CO₂ concentrations (20 and 50 cm) and surface CO₂ efflux during (A) June, (B) July, and (C) August 2005. Shaded boxes indicate significant differences. Dashed lines for 50 cm riparian soil CO₂ concentrations indicate that concentrations were not measurable due to groundwater saturation. n ranged from 24 for T7 versus T8 in June to 80 for T1 versus T2 in July.

Figure 9. Groundwater table (WT) dynamics and cumulative surface CO₂ efflux (Flux) at T1-4 and T6-4 from June 9 to August 31, 2005.

compared to west *versus* east in our study site. Riveros-Iregui and McGlynn (2009) found higher soil temperature on southeast *versus* northwest aspects in the same watershed as this study. However, their work collected measurements over much larger spatial extents (e.g. transects of hundreds of meters in length versus ~50 m in our study), including high-elevation ridges. Thus the smaller spatial extent of our study may not have fully captured the effect of aspect on soil respiration.

How does surface CO₂ efflux differ between two hydrologically distinct landscape positions: riparian (wet) and hillslope (dry) areas?

We found heterogeneity in efflux between riparian and hillslope zones within each transect, although this heterogeneity did not become apparent until measurements

Figure 10. Box-plots of cumulative growing season efflux (June 9 to August 31, 2005) from all riparian and hillslope locations. In the riparian zones, cumulative efflux was 1012 g CO₂ m⁻² during the 83-day growing season, whereas it was only 809 g CO₂ m⁻² during the growing season in the hillslopes.

were integrated across the entire growing season. Monthly surface CO₂ efflux was in general not significantly different between riparian and hillslope zones according to ANOVA results (Table II). This may be explained by the strong temporal heterogeneity in instantaneous efflux at monthly timescales, as well as the tradeoffs between the relative control of SWC on soil CO₂ production and transport (at shorter timescales) across the landscape. An increase in SWC can lead to higher soil CO₂ production (Davidson *et al.*, 1998, 2000), but simultaneously reduce soil gas diffusivity (Millington, 1959; Washington *et al.*, 1994; Moldrup *et al.*, 2000, 2001).

Figure 11. Cumulative growing season efflux (June 9 to August 31, 2005) from riparian and hillslope locations *versus* distance from channel head. Transects 1 and 2 (T1/T2) are the most upstream transects, whereas Transects 7 and 8 (T7/T8) are located furthest downstream.

At landscapes where SWC-mediated CO_2 production and transport are spatially variable, efflux equifinality (i.e. comparable outcomes with different combinations of the variables) may occur at short timescales (Pacific *et al.*, 2008). In the upper-Stringer Creek Watershed, riparian zone SWC was often in the intermediate range (defined as 40–60% in the TCEF) (Figure 3), optimal for soil CO_2 production (Davidson *et al.*, 2000; Schwendenmann *et al.*, 2003; Sjogersten *et al.*, 2006). However, increased riparian SWC also decreased soil gas transport (Millington, 1959; Washington *et al.*, 1994; Moldrup *et al.*, 2000, 2001), and riparian soil gas diffusivity rates were nearly an order of magnitude lower than in the adjacent hillslopes (Figure 3). In contrast, low hillslope SWC (median values of ~20%, Figure 3) resulted in decreased soil CO_2 production relative to the riparian zones, but higher soil gas transport. We suggest this tradeoff between the relative control of SWC on soil CO_2 production and transport resulted in riparian and hillslope zone equifinality in surface CO_2 efflux at monthly timescales.

However, higher riparian zone efflux ($p < 0.01$) becomes apparent when integrating to cumulative growing season efflux (June–August) (Figure 9). Cumulative efflux across the 83-day growing season was, on average, 25% higher in the riparian zones within each transect, suggesting increased riparian zone soil CO_2 production in response to higher SWC and higher and more persistent groundwater table development. Soil temperature was not significantly different between riparian and hillslope positions (Table II, Figure 3) and likely had little control on the spatial variability of soil respiration within each transect, which is consistent with other investigations (Pinol *et al.*, 1995; Xu and Qi, 2001; Scott-Denton *et al.*, 2003). Our results illustrate that large variability in efflux can exist across the landscape when measurements are integrated over longer time periods (e.g. growing season), supporting the use of cumulative fluxes as a tool in multi-site, landscape-

scale comparisons of soil respiration and other soil greenhouse gases (Pattey *et al.*, 2007; Pacific *et al.*, 2008; Riveros-Iregui *et al.*, 2008; Merbold *et al.*, 2009; Riveros-Iregui and McGlynn, 2009).

Differences in SOM across transects likely influenced the observed variability in riparian and hillslope soil respiration (Ostendorf, 1996; Ju and Chen, 2005; Sjogersten *et al.*, 2006). To address the influence of SOM on the spatial variability of soil respiration, we examined molar soil C:N ratios, which are often used as a predictor of decomposition rates (Enriquez *et al.*, 1993; Gholz *et al.*, 2000; Chapin *et al.*, 2002). Lower soil C:N ratios are generally more optimal for microbial decomposition (Enriquez *et al.*, 1993; Gholz *et al.*, 2000), with optimal ratios between 10:1 and 12:1 (Pierzynski *et al.*, 2000). Molar soil C:N ratios often approached this range in the riparian zones (Figure 2), and riparian cumulative efflux across the 83-day growing season was much higher than from the adjacent hillslope zones, where molar soil C:N ratios were generally above 20:1 (Figure 2). These differences in molar soil C:N ratios may be due to differences in above- and below-ground vegetation litter (Raich and Tufekcioglu, 2000; Smith and Johnson, 2004; Kellman *et al.*, 2007), as Riveros-Iregui and McGlynn (2009) found riparian vegetation had lower molar C:N ratios than hillslope vegetation in the same catchment. In addition, grassy riparian meadows have a higher allocation of photosynthate below the ground compared to the forested hillslopes (Raich and Tufekcioglu, 2000), which is often a large labile source of carbon for microbial activity (Baldocchi *et al.*, 2006). At the catchment scale, Riveros-Iregui and McGlynn (2009) found root density to be correlated with landscape position; however, we did not find significant differences between riparian and hillslope positions. Groundwater table dynamics may have influenced riparian and hillslope SOM variability, as frequent saturation retards microbial decomposition (Schlesinger, 1997). For example, soil C:N ratios were generally lower (more optimal) in the riparian zone on upstream transects (Figure 2), and we hypothesize that higher and more persistent groundwater table development in the riparian zones on upstream transects (Table I) led to higher riparian SOM (McGlynn and McDonnell, 2003; Hill *et al.*, 2004; Gurwick *et al.*, 2008).

Although soil C:N ratios are often used to infer decomposition rates, we point out that litter carbon quality (labile versus recalcitrant) may be a better predictor of decomposition rates (Melillo *et al.*, 1982) and should be accounted for in studies of the spatial variability of soil respiration. However, it was beyond the scope of this research to quantify the lability of soil C pools, and therefore molar soil C:N ratios were used to assess the influence of SOM on the spatial variability of soil respiration. Furthermore, it is possible that our measurements of C concentrations at 20 and 50 cm characterized more recalcitrant soil C pools, and future soil respiration studies should account for the labile C pool in the upper soil horizons, which could potentially vary by vegetation type and slope position across the landscape.

How can landscape metrics be used to explain dynamics between surface CO₂ efflux and SWC or soil temperature across multiple riparian and hillslope positions?

Our results demonstrate that consistent relationships between instantaneous surface CO₂ efflux and growing season soil temperature or SWC did not exist in the upper-Stringer Creek Watershed and suggest caution for transfer of such relationships across complex terrain. There were significant relationships between efflux and soil temperature or SWC across some transects (m² scale) (Figures 5 and 7); however, the relationships were very weak (low r^2 values), and one relationship could not be applied to all riparian and hillslope zones within and among transects. In fact, Riveros-Iregui and McGlynn (2009) found that across the entire upper-Stringer Creek Watershed (km² scale), efflux and soil temperature or SWC relationships were poor, and the only explanatory variable found for soil respiration was landscape morphology and structure. Quantification of relationships between efflux and soil temperature or SWC was based on instantaneous point measurements across a wide range of conditions in the upper-Stringer Creek Watershed. In contrast, landscape morphology and structure incorporates long-term hydrological dynamics, as wetter landscape positions often occur in areas with large UAA and gentle slopes (high TWI), and therefore may be a better predictor of soil respiration in complex landscapes than efflux and soil temperature or SWC relationships. The weakening of relationships between efflux and soil temperature or SWC as one moves from the small scale (~m²) to the large scale (~km²) demonstrates the role of multiple nested biophysical variables acting in space and time, which may result in confounding interactions between soil temperature, SWC, soil physical properties, and substrate availability, which are mediated by differences in landscape position. This weakening also reveals hierarchy in the biophysical controls of soil respiration across scales, and the implementation of such hierarchy into realistic process models capable of simulating and predicting soil respiration at multiple scales is simply necessary. Although there was not an overarching relationship between SWC and instantaneous surface CO₂ efflux in this study location (Figure 4), temporal integration revealed emergent patterns in SWC–efflux relationships not captured by instantaneous measurements (Riveros-Iregui and McGlynn, 2009), in which higher cumulative growing season efflux was generally observed in wetter landscape positions.

The wide range of SWC and efflux (Figure 4) contributed to the lack of an overarching relationship between efflux and SWC or soil temperature. For example, groundwater saturation inhibited soil respiration at many riparian zone locations early in the growing season. However, efflux often increased by up to an order of magnitude at these locations as the groundwater table declined and SWC decreased (Pacific *et al.*, 2008). Furthermore, in the hillslopes, T1–2 had unusually high efflux, likely in response to a fallen tree and related litterfall increase, which can stimulate soil respiration due

to increases in above- and below-ground carbon availability, soil temperature, and SWC. When this nest was removed from data analysis (denoted by dashed regression line in Figure 4), the relationships became weaker, and in the case of surface CO₂ efflux *versus* SWC, they were not significantly different. Our results demonstrate the importance of measurement collection across wide ranges of landscape positions, and exercising caution when applying empirical relations (e.g. soil temperature–SWC–efflux) in models of soil respiration across large spatial scales.

Implications for up-scaling of soil respiration measurements

In order to gain understanding of soil respiration variability from the point to the watershed or ecosystem scale, it is necessary to collect and analyze measurements over a wide range of landscape positions, spatial and temporal scales, and across wide ranges of biophysical gradients. As such data collection is demanding and often unfeasible, studies of landscape-scale soil respiration must employ techniques and experimental designs that bridge the gap between point and landscape scale measurements. In tandem with field observations, terrain analysis and landscape metrics (e.g. UAA and slope estimation) and remote sensing techniques are useful tools to scale point soil respiration measurements to larger areas, and to bring biophysical relationships found at smaller scales into larger, geomorphic contexts.

Soil respiration and respiration-driving variables differed across landscape positions with large differences in UAA, slope, TWI, and groundwater table dynamics in the upper-Stringer Creek Watershed. In the riparian zones, soil CO₂ concentrations ranged broadly (often by over 20 000 ppm, Figure 4), and cumulative efflux during the growing season was generally higher and had a wider range than the adjacent hillslopes along each transect (Figure 10). These trends were potentially in response to the wider range of riparian SWC (~35–85%, Figure 3), more variable groundwater table depths, and more narrow (optimal) molar soil C:N ratios (Figure 2). This was in contrast to the hillslopes, where a smaller range in cumulative efflux was observed, and the range of soil CO₂ concentrations did not exceed 5000 ppm (Figure 3). At these hillslope locations, groundwater table development was not observed, the range of SWC was low (10–40%, Figure 3), and molar soil C:N ratios were higher and less optimal (Figure 2). Furthermore, higher cumulative efflux was found on upstream transects (Figure 11), where TWI values were larger in response to higher UAA and gentler slopes (Table I), and the groundwater table was relatively high and more persistent. The lowest cumulative efflux was measured on downstream transects where low UAA and steep slopes resulted in a low TWI, and deeper groundwater tables in the riparian zones were observed. These findings highlight the potential of landscape context for interpreting point and plot scale measurements of soil respiration. This concept is widely used in hydrological modeling, in which landscape position similarity is

often related to hydrological behavior similarity (McGlynn *et al.*, 2004; Beighley *et al.*, 2005; Seibert and McGlynn, 2005). Our findings indicate that landscape position may also be related to carbon dynamics, or “carbon context,” to interpret and extrapolate point-scale measurements of soil respiration to larger landscapes. Therefore, landscape analysis can provide a way forward in up-scaling soil respiration measurements and be useful when modeling soil respiration to reduce potentially large uncertainty in scaling point measurements to landscape and regional scales.

Conclusions

Measurements of growing season (June–August) SWC, soil temperature, groundwater dynamics, soil C and N concentrations, soil CO₂ concentrations, and surface CO₂ efflux across eight topographically distinct riparian-hillslope transitions within the upper-Stringer Creek Watershed demonstrated that:

1. Landscape attributes such as slope and UAA impacted groundwater table dynamics and affected soil respiration-driving variables such as SWC and SOM, and therefore must be accounted for when investigating landscape-level dynamics of biogeochemical fluxes.
2. Instantaneous soil surface CO₂ efflux was not significantly different both within and among riparian and hillslope zones at monthly timescales according to ANOVA analysis. This was likely the result of different mechanistic controls on CO₂ production and transport and efflux equifinality at short timescales.
3. Cumulative growing season efflux was 25% higher in the riparian zones than the adjacent hillslopes, which demonstrates that large differences in soil respiration existed between riparian and hillslope zones over longer timescales, and highlights the importance of temporal integration in comparisons of surface CO₂ efflux across landscapes.
4. Landscape position can be related to both soil water and carbon dynamics and may be a valid approach to interpret and extrapolate point/plot scale measurements of soil respiration to larger landscapes.

Our findings indicate that landscape position and contextual variables such as slope and UAA can influence soil respiration. Differential controls of respiration drivers such as SWC, SOM availability, groundwater table dynamics, and soil gas diffusivity may lead to organized heterogeneity in cumulative surface CO₂ efflux as a function of landscape position. Our results highlight the need for further investigations of the spatial variability of soil respiration in complex terrain across a range of biophysical gradients, groundwater dynamics, and landscape positions in order to elucidate the primary controls of respiration heterogeneity across the landscape.

Acknowledgments —We gratefully acknowledge field assistance from Kelsey Jencso, Becca McNamara, Kelley Conde, and Austin Allen. We thank the Tenderfoot Creek Experimental Forest and the USDA, Forest Service, Rocky Mountain Research Station, especially Ward McCaughey, for logistical support and research site access. This work was funded by the NSF Integrated Carbon Cycle Research Program (ICCR, NSF Grant EAR0404130, EAR0403924, and EAR0403906) and fellowships awarded to V. J. Pacific from the Big Sky Institute NSF GK-12 program, Inland Northwest Research Alliance (INRA), and the Montana Water Center Student Research Grant Program. D. A. Riveros-Iregui acknowledges support from the 2007 American Geophysical Union Horton Research Grant, an NSF Doctoral Dissertation Improvement Grant (DEB-0807272), and the USGS 104b Grant Program, administered by the Montana Water Center. Airborne laser mapping was provided by the NSF-supported National Center for Airborne Laser Mapping (NCALM) at the University of California, Berkeley.
