Abstract
Nanotwinned metals exhibit outstanding radiation tolerance as twin boundaries effectively engage, transport and eliminate radiation-induced defects. However, radiation-induced detwinning may reduce the radiation tolerance associated with twin
boundaries, especially at elevated temperatures. Here we show, via *in-situ* Kr ion irradiation inside a transmission electron microscope, that 3 at. % Fe in epitaxial nanotwinned Cu (Cu<sub>97</sub>Fe<sub>3</sub>) significantly improves the thermal and radiation stability of nanotwins during radiation up to 5 displacements-per-atom at 200 °C. Such enhanced stability of nanotwins is attributed to a diffuse 9R phase resulted from the dissociation of incoherent twin boundaries in nanotwinned Cu<sub>97</sub>Fe<sub>3</sub>. The mechanisms for the enhanced stability of twin boundaries in irradiated nanotwinned alloys are discussed. The stabilization of nano-twins opens up opportunity for the application of nanotwinned alloys for aggressive radiation environments.

**Keywords:** Nanotwins, Radiation, Detwinning, 9R phase, Solute drag

### 1. Introduction

Energetic particle irradiation of metallic materials produces large amounts of point defects (interstitials and vacancies), which can further aggregate into extended defect clusters in the form of dislocation loops [1–5], stacking fault tetrahedrons (SFTs) [6–11] or cavities [12–23], resulting in microstructural evolution and degradation of mechanical properties [24–29]. It has been proposed that the radiation tolerance of materials can be significantly improved by using defect sinks [30–35]. Nanostructured materials contain abundant defect sinks and have shown enhanced radiation tolerance [27,36–39]. Grain boundaries (GBs) are one of the effective defect sinks [40], and nanograin (NG) materials show enhanced radiation tolerance compared with their coarse-grained (CG) counterparts as evidenced by fewer defects [41,42], reduced radiation hardening [43], stronger resistance to amorphization [44] and much less void swelling [14,45]. However, due to the high excess energy of conventional high-angle GBs, NG materials often suffer from poor thermal stability [46], and radiation-induced grain coarsening can occur even at room temperature [47]. Design of nanomaterials that can survive harsh radiation environments at elevated temperatures remains a major challenge [31,48].

Nanotwinned (NT) metals have raised significant interest due to their unique combination of remarkable mechanical properties [49–53] and superior thermal stability [54,55], as well as enhanced radiation tolerance [56–59]. *In-situ* studies have revealed that twin boundaries (TBs) can frequently interact with radiation-induced defects and tailor their formation and distribution [56,57,60–62]. For instance, fewer
Defects are formed in NT Cu than in CG Cu under the same radiation conditions [57]. In addition, SFT, a notorious defect, can be destructed by interacting with TBs [56].

In NT metals with face centered cubic (FCC) structure, there are two major types of TBs: Σ3 {111} coherent twin boundaries (CTBs) and Σ3 {112} incoherent twin boundaries (ITBs) [63,64]. Extensive studies have shown that ITBs, containing arrays of Shockley partials, can migrate under irradiation [65], stress [66], high temperature [67] and electrical field [68]. As a result, detwinning occurs through ITB migration, decreases twin density, and compromises the performance of NT materials [69,70]. Therefore, to further improve the radiation tolerance of NT metals, it is of great significance to stabilize TBs, especially the highly mobile ITBs.

In this paper, we successfully synthesized epitaxial NT-Cu$_{97}$Fe$_3$ and compared its radiation response to that of NT-Cu by using in situ Kr$^{++}$ irradiation at 200 °C inside a transmission electron microscope (TEM). The in-situ studies show that, in contrast to rapid detwinning in NT-Cu, the sharp ITBs in NT-Cu$_{97}$Fe$_3$ evolve into diffuse 9R phase and are highly stable against radiation at elevated temperatures. ITB migration velocity in NT-Cu$_{97}$Fe$_3$ is significantly lower than that in NT-Cu, lending experimental support for stabilizing NT structures via the introduction of certain solutes. In-situ studies also show that ITBs and CTBs in NT-Cu$_{97}$Fe$_3$ actively engage and eliminate radiation-induced defects.

2. Experimental methods

Highly-textured NT-Cu and NT-Cu$_{97}$Fe$_3$ alloy films, ~2 mm thick, were deposited on HF etched Si (110) substrates by using direct current magnetron sputtering technique at room temperature. Pure Cu (99.995%) and Fe (99.99%) targets were used for sputtering, and the chamber was evacuated to a base pressure ~ 5 × 10$^{-8}$ torr prior to deposition. During deposition, ~1.2 × 10$^{-3}$ torr Ar working pressure was used, and the deposition rate was controlled at ~0.6 nm/s. After depositions, the TEM specimens for irradiations were prepared by polishing, dimpling and low energy (3.5 keV) Ar ion milling. Subsequent heavy ion (1 MeV Kr$^{++}$) irradiations on the cross-sectional TEM samples were conducted in the Intermediate Voltage Electron Microscope.
(IVEM) at Argonne National Laboratory, where an ion accelerator was attached to a Hitachi-9000 TEM microscope. More specific information regarding such \textit{in-situ} heavy ion irradiation technique has been described elsewhere [71]. Before irradiation, the TEM specimens were annealed at 200 °C inside the IVEM column for 30 min. Then it was followed by Kr$^{++}$ irradiations at 200 °C. During the irradiation, a CCD camera was utilized to capture videos at 15 frames/s.

The texture of as-deposited films was analyzed using an X-ray diffraction technique on a Panalytical Empyrean X’pert PRO MRD diffractometer with a Cu Kα$_1$ source. All the as-prepared and irradiated TEM samples were examined by a Thermo Fisher Scientific/ FEI Talos 200X analytical TEM with Super-X EDS detectors. The Stopping and Range of Ions in Matter (SRIM) simulation with Kinch-Pease method was used to estimate the radiation damage in unit of displacements-per-atom (dpa) [72,73]. As the Fe content is low in NT-Cu$_{97}$Fe$_3$, the radiation damage profile was simulated based on pure Cu. SRIM simulations calculated for pure Cu (Supplementary Fig. S1) show that ~99% of Kr ions have penetrated through TEM foils, leaving most radiation damage behind. The average ion dose rate was ~2.5 × 10$^{-3}$ dpa/s, and the maximum radiation damage was 5 dpa with a total fluence of 1 × 10$^{15}$ ions/cm$^2$.

3. Results

\textbf{Fig. 1} demonstrates the texture analysis of as-deposited Cu and Cu$_{97}$Fe$_3$ films. The conventional two-theta scans in Fig. 1(a) show that both films are highly (111) textured. The Phi scans in Fig. 1(b) show the diffraction peaks from both twin and matrix orientations with nearly identical intensity, indicating the formation of significant growth twin structures.

\textbf{Fig. 2} compares the microstructural evolution of NT-Cu and Cu$_{97}$Fe$_3$. Cross-section TEM micrographs show that nanotwins in Cu have a smaller average twin spacing, ~5 nm, comparing with ~14 nm for the NT-Cu$_{97}$Fe$_3$. The twin spacing here is defined as the distance between two adjacent CTBs [57]. No obvious TB migrations were observed during the annealing process at 200 °C for 30 min.
However, once radiation started, detwinning took place in NT-Cu, giving rise to significant increase in twin spacing, as shown in Fig. 2(a1-a4). In contrast, nanotwins in NT-Cu$_{97}$Fe$_3$ exhibited superior stability, and most of TBs survived after irradiation to 5 dpa, as shown in Fig. 2(b1-b4). See supplementary video SV1 for more details. Statistical studies in Fig. 2(c1) and (c2) show the irradiation-induced prominent increase of average twin spacing ($\lambda_{ave}$) in NT-Cu from 5 to 29 nm (after 5 dpa), while the $\lambda_{ave}$ in NT-Cu$_{97}$Fe$_3$ increased slightly from 14 to 16 nm.

Fig. 1. Texture analysis of XRD profiles of sputtered Cu (blue) and Cu$_{97}$Fe$_3$ films (red) on Si (110) substrates. (a) Two-theta scans showing strong (111) texture along growth direction for both films. (b) Phi-scan profiles with a six-fold symmetry, indicating a significant fraction of twins in both Cu and Cu$_{97}$Fe$_3$ films. M and T denote three matrix and twin peaks, respectively.
The irradiation-induced detwinning event is attributed to defect-TB interactions. Fig. 3 compares the irradiation response of CTBs. It has been found that CTBs can become curved to accommodate defect clusters formed in the vicinity. Since defect clusters are often small and have transient lifetime [62,74], they introduce local and temporary distortion (in form of curvatures) along CTBs. As shown in Fig. 3, the local curved CTBs were frequently observed in both cases and they exhibited surprising resilience and self-healing ability. In NT-Cu at ~1.8 dpa in Fig. 3(a1), the CTBs appeared straight. After 6 s in Fig.
3(a2), the CTB became curved. However, by 19 s in Fig. 3(a3), the distorted CTB had recovered and restored its straight appearance. Similarly, in NT-Cu$_{97}$Fe$_3$, the upper CTB appeared straight initially (~2.5 dpa) in Fig. 3(b1). At 6 s in Fig. 3(b2), a local distortion was identified at position 1. By 25 s in Fig. 3(b3), the distortion 1 had recovered, while a new distortion at position 2 occurred due to the interaction between the CTB and a defect cluster. At 27 s in Fig. 3(b4), the distortion 2 also recovered. More detailed information can be found in supplementary videos of SV2 and SV3.

By comparison, the ITBs in irradiated NT-Cu frequently migrated and showed prominent thickness-dependence. When the twin thickness ($t$) is several nanometers, ITBs migrate drastically. As shown in Fig. 4(a), an ultrafine twin (3 nm in thickness) was 79 nm long at 0 s (~0.1 dpa). At 2 s in Fig. 4(b), its ITB migrated abruptly by 38 nm. By 10 s in Fig. 4(c), the twin had fully retracted (disappeared). More detailed information can be found in Supplementary Video SV4.
However, when \( t > 10 \) nm, ITB migration often starts from twin corners. As shown in Fig. 5(a1) at \( \sim 3.1 \) dpa, \( T_1 \) (\( t_1 = 13 \) nm) had a vertical ITB with two right corners. In 65 s in Fig. 5(a2), the lower right corner retracted leftward by 10 nm and continued to retract by 13 nm after 69 s in Fig. 5(a3). Meanwhile, the upper corner experienced detwinning by 6 nm by 65 s, and recovery by 76 s as shown in Fig. 5(a4). With further irradiation to 126 s, both corners retracted by 14 nm and 20 nm, respectively, leading to a sharp tip in the middle of the ITB as shown in Fig. 5(a5). The protrusion remained unchanged, until significant detwinning occurred instantaneously at 160 s in Fig. 5(a6).

By comparison, the ITBs in NT-Cu\(_{97}\)Fe\(_3\) remained stable regardless of twin thickness. For instance, three typical twins (T2, T3 and T4) with various thickness were monitored during irradiation (2.4–2.8 dpa) as shown in Fig. 5(b1-b6). No ITB migration was observed, even for the ultrafine twin T2 (\( t_2 = 3 \) nm). Note that the ITB of T3 (\( t_3 = 12 \) nm), as shown in the box in Fig. 5(b1), was initially sharp, but subsequently dissociated into a 3-nm-wide diffuse ITB after 98 s in Fig. 5(b4). The diffuse ITB extended further to be 4 nm wide, as shown in Fig. 5(b6). T4 (\( t_4 = 27 \) nm) has a diffuse ITB, which is 7 nm wide and its width remained unchanged during irradiation. The diffuse ITB absorbed a large defect cluster, an SFT in its vicinity, as shown in Fig. 5(b2-b3). Meanwhile, CTBs also actively engaged in absorbing defects and became

curved locally, as marked by the green arrows in Fig. 5(b2-b6). More details related to the irradiation responses of ITBs in NT-Cu and NT-Cu$_{97}$Fe$_3$ can be found in supplementary videos SV5 and SV6.

High-resolution TEM (HRTEM) experiments were performed to examine the evolution of TBs in irradiated NT-Cu and NT-Cu$_{97}$Fe$_3$ along <110> zone axis. Before irradiation, as shown in Fig. 6(a1) and (b1), the CTBs are sharp, and the ITB width is narrow, ~1 nm in both systems. After irradiation to 5 dpa, numerous stacking faults (SFs) emerged in NT-Cu along CTBs, and the thickness of SF ribbon is ~2 nm, whereas the thickness of CTBs in irradiated NT-Cu$_{97}$Fe$_3$ increases slightly in Fig. 6(b2). The ITBs of irradiated NT-Cu remain narrow (~1 nm), while the irradiated ITBs in NT-Cu$_{97}$Fe$_3$ have dissociated into a slab bounded by two curved phase boundaries. A typical example of the dissociated ITB in NT-Cu$_{97}$Fe$_3$ is shown in Fig. 6(b2). The lower-left

![Fig. 6. HRTEM micrographs of TBs and irradiation-induced defects in NT-Cu and NT-Cu$_{97}$Fe$_3$ before and after irradiation (5 dpa). (a1) and (b1) TBs are sharp in both systems prior to irradiation. (a2) In irradiated NT-Cu, ITBs remain sharp, but CTBs are decorated with SF ribbons. (a3) Irradiation-induced triangular SFTs in NT-Cu. (b2) Radiation of NT-Cu$_{97}$Fe$_3$ induces broad ITBs, identified as 9R; but CTBs remain largely unchanged. (b3) The irradiated NT-Cu$_{97}$Fe$_3$ contains SFTs and prismatic dislocation loops.](image-url)
inset shows that the dissociated ITB region has a repeatable pattern, identified as 9R phase, which is also confirmed by the inserted fast Fourier transform (FFT). Note that in Fig. 5(b6) the dissociated ITB region of T4 is wider than that of T3, and it appears that the width of dissociated ITBs varies with twin thickness as will be shown later. HR-TEM images in Fig. 6(a3) and (b3) also reveal that the defect clusters in NT-Cu are dominated by high-density triangular SFTs, whereas the defects in NT-Cu include SFTs and prismatic dislocation loops.

*In-situ* TEM technique permits the determination of ITB migration velocity ($V_{\text{ITB}}$). Fig. 7(a) indicates that irradiation induces ITB migration in NT-Cu, and the $V_{\text{ITB}}$ decreases with increasing thickness ($t$). Moreover, $V_{\text{ITB}}$ of NT-Cu increases significantly with increasing irradiation temperature (to 200 °C). In contrast, the ITBs in NT-Cu$_{97}$Fe$_3$ barely migrate during irradiation at 200 °C. In addition, Fig. 7(b) illustrates that the ITB width ($W_{\text{ITB}}$) of irradiated NT-Cu has little variation and remains $\sim$1 nm. In comparison, the $W_{\text{ITB}}$ of irradiated NT-Cu$_{97}$Fe$_3$ elevates with increasing $t$, ranging from 3 to 10 nm.

**Fig. 7.** Irradiation-induced evolution of ITB velocity ($V_{\text{ITB}}$) and width ($W_{\text{ITB}}$), plotted as a function of twin thickness ($t$) for NT-Cu and NT-Cu$_{97}$Fe$_3$. (a) $V_{\text{ITB}}$ increases rapidly with decreasing twin thickness for NT-Cu or at higher irradiation temperature. A reference black data set of NT-Cu irradiated at room temperature (RT) is also plotted [57]. The $V_{\text{ITB}}$ is extremely low and barely changes for NT-Cu$_{97}$Fe$_3$ even for finest twins ($t < 5$ nm). (b) $W_{\text{ITB}}$ of NT-Cu remains constant, $\sim$1 nm, after radiation. However, the $W_{\text{ITB}}$ of the irradiated NT-Cu$_{97}$Fe$_3$ increases monotonically with $t$. 
4. Discussion

4.1. Thickness and temperature dependent detwinning in NT-Cu

Our *in-situ* TEM observations reveal that CTBs exhibit surprising resilience and self-healing ability in response to irradiation, as shown in Fig. 3. This is determined by the nature of irradiation-induced defect clusters and interactions with CTBs. Since defect clusters are often small and have transient lifetime [62,74], they introduce only local and temporary distortion (in form of curvatures) along CTBs. Moreover, previous studies show that the SFTCTB interactions can lead to the formation of multiple SFs [56,74]. This is also confirmed by our post-irradiation HRTEM analysis in Fig. 6(a2) and Fig. 6(b2), which show that CTBs appear ‘thicker’ after irradiation. Our *in-situ* observations also show that irradiation-induced detwinning occurs primarily through ITB migration. The ITBs in FCC Cu are composed of three types of mobile Shockley partials on successive (111) planes [75–77]. Fig. 8(a1) schematically illustrates the ITB structure, including one pure edge partial ($b_1$) and two mixed partials ($b_2$ and $b_3$). This dislocation model has the advantage of relating ITB structure to its migration or dissociation.

ITBs in pure metals can migrate under shear stress through the collective glide of partials [78,79], known as the phase-boundary-migration (PBM) mechanism [80,81]. Impingement of defect clusters during radiation can enhance TB migration by lowering the activation energy barrier for dislocation glide [82]. Consequently, heavy ion irradiation induces ITB migration and detwinning in NT-Cu, as shown schematically in Fig. 8(a1–a3). The ITB migration velocity, $V_{ITB}$, in NT-Cu is closely associated with twin thickness ($t$). The driving force, $2\gamma_{Twin}/t$, for ITB migration increases with decreasing $t$ [57], and $\gamma_{Twin}$ is twin boundary energy for S3 (111), approximately $1/2$ of $\gamma_{SF}$ with $\gamma_{SF}$ being the stacking fault energy (SFE). When $t$ is comparable to the size of defect clusters, the entire ITB can migrate rapidly (see Fig. 4), and thus a fine twin is more likely to undergo detwinning, as shown in Fig. 8(a2–a3). For a thicker twin ($t > 10$ nm), however, detwinning often starts from twin corners, presumably because the migration of ITBs from corners does not change the total length or energy of the TBs [67]. If this analysis is correct, the reverse process, twinning from corner should also occur when local shear stress reverses its sign. Indeed, this hypothesis has been confirmed by our *in-situ* TEM observations in Fig. 5(a3–a4).
Fig. 8. Irradiation responses of TBs in NT-Cu and NT-Cu$_{97}$Fe$_3$. (a1-a3) Irradiation-induced ITB migration and detwinning in NT-Cu. (b1-b7) DFT calculations of the energetics of Fe solute in Cu lattice, SF plane, CTB and ITB. (c1-c3) Irradiation of NT-Cu$_{97}$Fe$_3$ induces dissociation of ITBs into 9R phase, which is pinned by Fe solute atoms, and thus prohibit detwinning. In addition, irradiation can cause CTB distortions in form of curved TBs in both NT-Cu and NT-Cu$_{97}$Fe$_3$. 

1. Irradiation-induced ITB migration and detwinning in NT-Cu

2. Energetics of Fe solute in Cu matrix

3. Irradiation-induced ITB dissociation into 9R phase in NT-Cu$_{97}$Fe$_3$
At elevated temperatures, the Shockley partials possess higher mobility due to a reduced friction stress, and the driving force for detwinning also increases, and thus the ITB migration velocity increases further in NT-Cu.

4.2. Energetics of Fe solutes in Cu

*In-situ* studies show that a small amount of Fe solute atoms (~3 at. %) in NT-Cu can significantly enhance TBs stability against irradiation at elevated temperatures. First, there is much less detwinning in the irradiated NT-Cu$_{97}$Fe$_{3}$ alloy irrespective of original twin thickness (see Fig. 2). Many fine twins survived irradiation, in drastic contrast to the rapid detwinning in NT-Cu. Second, the TB migration velocity in NT-Cu increases sharply with decreasing twin thickness. In the irradiated NT-Cu$_{97}$Fe$_{3}$, however, TBs barely migrate. Third, our study shows that ITB migration velocity in NT-Cu increases significantly during irradiation at elevated temperatures. Irradiation of NT-Cu$_{97}$Fe$_{3}$ at the same temperature leads to little sign of detwinning.

To understand the influence of Fe on TB stability, we examined the energetics of Fe solute in Cu lattice with respect to their locations according to density functional theory (DFT) calculations. The detailed calculation procedure can be found in the Supplementary Information. The results show that the formation energy ($E_f$) of a single Fe solute is 1.409 eV for substitutional site (Fig. 8(b1)), 5.427 eV for tetrahedral interstitial (Fig. 8(b2)) and 5.225 eV for octahedral interstitial site (Fig. 8(b3)). In comparison, $E_f$ of Cu self-interstitial atom for tetrahedral and octahedral site is 3.901 and 3.488 eV, respectively, much lower than that of Fe interstitial. These results show that Fe solute prefers to stay at substitutional site and can hardly diffuse via interstices. $E_f$ of four Fe atoms at nearest substitutional sites is 1.533 eV. Therefore, the segregation of Fe atoms is energetically preferred. But, as mentioned earlier, the diffusion of Fe is energetically difficult, so the Fe solutes are expected to be homogeneously distributed in Cu matrix during deposition, which is consistent with our EDS analysis shown in Supplementary Fig. S2.
The formation energies of Fe solutes at SF plane, CTB (Fig. 8(b4)) and ITB (Fig. 8(b5)) are also calculated. As shown in Fig. 8(b6), the calculated stacking fault energy ($\gamma_{SF}$) of pure Cu is 38.64 mJ/m$^2$. If one of the 16 Cu atoms on a fault plane is replaced by an Fe atom, the stacking fault energy increases to 47.38 mJ/m$^2$. For the model with CTB, the segregation energy of Fe, the energy change for moving Fe atom from defect free crystal to the twin boundary, is 0.048 eV, which suggests that the CTB is not the preferred site for Fe solutes. The energy barrier of CTB migration shown in Fig. 8(b7) increases by adding Fe solutes. In addition, the formation energies of Fe solutes in ITB at substitutional and interstitial sites are 0.623–0.824 eV and 1.669–1.750 eV, respectively. The lower formation energies indicate that ITBs are thermodynamically favorable sites for Fe solutes.

4.3. Mechanisms of irradiation stability of nanotwins in NT-Cu$_{97}$Fe$_3$

Post-radiation TEM studies in Fig. 6(b2) show that the ITBs in irradiated NT-Cu$_{97}$Fe$_3$ dissociate into a broad 9R phase, bounded by two phase boundaries. Furthermore, the width of 9R phase increases with increasing twin thickness, as illustrated in Fig. 7(b). Such an observation has profound impact on TB stability and radiation tolerance of irradiated NT Cu–Fe alloys and warrants further discussions.

First, the ITB dissociation occurs through the glide of arrays of Shockley partials [77,83]. When an ITB is subjected to shear, $\tau_{yx}$, the glide force on the partial dislocation $b_1$ is expressed by Ref. [81]:

$$F_x = -\tau_{yx} b_1 + F_{b_1b_2} + F_{b_1b_3} + \gamma_{SF} + F_p$$  \hspace{1cm} (1)

The first term on the right in Equation (1) represents the driving force for migration of $b_1$ under external shear stress. The resistance for the migration of $b_1$ arises from $F_{b_1b_2}$ and $F_{b_1b_3}$, the attractive force between $b_1$ and $b_2$ ($b_3$); the stacking fault energy, $\gamma_{SF}$, and the friction force due to Peierls stress, $F_p$. During irradiation of monolithic NT-Cu, defect clusters will generate a shear stress that drives the migration of ITBs [60]. The $\gamma_{SF}$ of Cu is low, and $F_p$ is typically negligible in Cu, and thus the resistance to the migration of TB is relatively low.

Our DFT calculations show that Fe can increase the $\gamma_{SF}$, consequently the resistance for ITB migration increases substantially in NT
Cu$_{97}$Fe$_3$ alloys. Also the growth twin density in as-deposited NTCu$_{97}$Fe$_3$ is lower than that in as-deposited NT-Cu, in agreement with the twin nucleation theory in sputtered films that suggests a higher $\gamma_{SF}$ leads to a lower probability of twin nucleation [51]. Moreover, post-radiation TEM studies show that a majority of defect clusters in irradiated NT-Cu are SFTs; however, both SFTs and large prismatic dislocation loops are observed in irradiated NTCu$_{97}$Fe$_3$ alloy. Prismatic loops are often observed in irradiated materials with higher $\gamma_{SF}$ [84].

Second, it has been shown in monolithic NT metals, that the edge Shockley partial and two mixed partials migrate together due to their mutual attractive forces [81]. MD simulations have shown that the edge partial, $b_1$, tends to migrate first under shear. The attractive force between $b_1$ and $b_2$ ($b_3$) then drags the two mixed partials to move together, leading to the migration of ITBs. The current study shows that radiation of NT-Cu did not change the width of ITBs, ~ 1 nm. However, the width of ITBs in irradiated NTCu$_{97}$Fe$_3$ increases rapidly during irradiation to 3–10 nm. Thus, the attractive force between $b_1$ and $b_2$ ($b_3$) decreases, making the migration of ITBs difficult. Previous in-situ TEM studies showed that broad 9R in twinned Ag is unstable, and can “zip” together into a sharp ITB under e-beam irradiation to relax internal stress, and migrates rapidly thereafter [83]. As the 9R phase is stabilized by Fe solute and remains broad in the irradiated NT-Cu$_{97}$Fe$_3$, its migration becomes difficult.

Third, our in-situ radiation studies in Fig. 5(b1-b6) show that 9R phase in NT Cu$_{97}$Fe$_3$ is an excellent defect sink, as it can capture and absorb defect clusters, such as dislocation loops and SFTs. Consequently, the 9R phase becomes broader, as schematically shown in Fig. 8(c2). Since thicker twins have greater probability to capture defect clusters [74], the width of their 9R increases with twin thickness, as shown in Fig. 8(c3). 9R and CTBs can thus form an effective defect-sink network, contributing to the remarkable radiation tolerance of NT-Cu$_{97}$Fe$_3$ alloy.

The dissociation of an ITB into 9R phase has been reported in pure Au [85], Ag [86] and Cu [76] with low $\gamma_{SF}$ [87]. It has been concluded that the degree to which ITBs dissociate depends not only on the local stress state within specimen but also on the stacking fault energy [88]. Our study suggests that using appropriate solutes may effectively stabilize 9R phase in various metallic materials. Recently, high-density
9R phase has also been reported in sputtered NT Al-Fe [89], Al-Ti [90] and Al-Mg [91] solid solution alloys. These studies reveal that 9R phase is also beneficial for improving the mechanical properties (high strength and plasticity) of NT metals. The current study suggests that 9R phase coupled with the selection of appropriate solutes may significantly enhance the radiation resistance and stability of nanotwins in a broad range of metallic materials.

5. Conclusions

Nanotwinned Cu and Cu97Fe3 were in-situ irradiated using Kr++ at 200 °C under the same condition inside a transmission electron microscope. Monolithic NT-Cu experiences prominent detwinning through ITB migration, whereas the nanotwins in NT-Cu97Fe3 alloy remain stable. The outstanding radiation and thermal stability of TBs in NT-Cu97Fe3 arise from the dissociation of ITBs into a broad 9R phase, which also actively absorbs radiation-induced defects. The enhanced twin stability is also attributed to the drag effect of Fe solutes on the dissociated ITBs. These findings provide an important step forward towards the design of stable radiation-resistant nanotwinned alloys under extreme environments.

Acknowledgments — We acknowledge primary financial support by NSF-CMMI-MOM Program under grant no. 1728419. The work on fabrication of nanotwinned metals is supported by DOE-BES under grant no. DESC0016337. We also thank Peter M. Baldo and Edward A. Ryan at Argonne National Laboratory for their help during in-situ radiation experiments. The IVEM facility at Argonne National Laboratory is supported by DOE-Office of Nuclear Energy. Accesses to the Microscopy Centers at Purdue University and the DOE Center for Integrated Nanotechnologies managed by Los Alamos National Laboratory is also acknowledged. D. Y. Xie and J. Wang acknowledge the support by the Nebraska Center for Energy Sciences Research, University of Nebraska–Lincoln. Atomistic simulations were completed utilizing the Holland Computing Center of the University of Nebraska, which receives support from the Nebraska Research Initiative. We also acknowledge the support by Center for Nanoscale Materials (CNM) at Argonne National Laboratory under CNM Proposal 52081.
Appendix A. Supplementary data to this article follows the References.

DFT calculation method

The Vienna ab-initio simulation package (VASP) is used to perform calculation with projector augmented wave (PAW) method[1] and generalized gradient approximation (GGA) approach[2]. During the calculation, spin polarization is considered, and the Perdew-Burke-Ernzerhof (PBE) function[3] is employed. The pseudopotential with electron configuration $3d^{10}4s^1$ and $3d^74s^1$ is used to describe the behavior of Cu and Fe ion, respectively[4]. The bulk properties are computed with a $3\times3\times3$ supercell containing 106-108 Cu atoms and 0-4 Fe atoms. The slab models for a coherent twin boundary (CTB) and stacking fault (SF) have 10 layers on (111) plane. In each plane, there are 16 atoms. The (112) ITB slab models are constructed with 3 layers on (111) plane and 6 layers on (110) plane. The model contains 104-105 Cu atoms and 1 Fe atom. The first Brillouin zone of bulk models and slab models are sampled with a $3\times3\times3$ and a $4\times4\times1$ M-P k-mesh[5]. A 400eV cut-off energy is used for all calculations in this study. The convergence criteria of geometry optimizations and self-consistent calculations is 0.01eV/Å and $10^{-5}$eV respectively. To verify the rationality of parameters used in computations, the properties of copper and iron are calculated with unit cell sampled with a $9\times9\times9$ M-P k-mesh. For copper, the calculated lattice constant is 3.629 Å and the cohesive energy is 3.48 eV. For BCC iron, the lattice constant is 2.2866 Å and the cohesive energy is 4.855 eV. These properties are consistent with previous studies[6-8].

Supplementary Video Captions

Supplementary Video SV1. Comparison of the evolution of twins in NT Cu (left) and NT Cu$_{97}$Fe$_3$ (right) under Kr$^{++}$ irradiation at 200 °C up to 1.2 dpa. Note that the videos have been accelerated by 16 times.

Supplementary Video SV2. Self-healing of CTBs in irradiated NT-Cu from 1.80 to 1.81 dpa. The video corresponds to the snapshots in Figure 3 (a1-a3).

Supplementary Video SV3. Self-healing of curved CTBs in irradiated NT-Cu$_{97}$Fe$_3$ from 2.50 to 2.51 dpa. The video corresponds to the snapshots in Figure 3(b1-b4).

Supplementary Video SV4. Drastic ITB migration of an ultrafine twin (~3 nm in thickness) in irradiated NT Cu at ~ 0.1 dpa. The video corresponds to the snapshots in Figure 4.

Supplementary Video SV5. Gradual migration of a long ITB of a thick twin (~13 nm in thickness) in NT-Cu from 3.1 to 3.5 dpa. The video corresponds to the snapshots in Figure 5(a1-a6). Note that the video has been accelerated by 8 times.

Supplementary Video SV6. The absorption of a defect cluster by a diffuse ITB in NT-Cu$_{97}$Fe$_3$ from 2.4 to 2.8 dpa. The video corresponds to the snapshots in Figure 5(b1-b6).
