Abstract. Siderophores are low molecular mass compounds used by many microorganisms to scavenge dissolved iron, which is typically rare in environments. *Pseudomonas aeruginosa* (PAO1) was exposed to metals and methyl viologen in low-iron medium in order to monitor the abundance of a specific siderophore (pyoverdine) and monitor growth over time. In this study it was discovered that cadmium can stimulate pyoverdine abundance. Cadmium may interact with and sequester the Fur regulatory protein, which represses siderophore synthesis under conditions of iron sufficiency. Mercury did not stimulate pyoverdine production at concentrations that strongly inhibited bacterial growth, suggesting that pyoverdine production is not governed as part of a general stress response. Methyl viologen is an oxygen radical generator, and it was discovered that exposure to it decreased pyoverdine production. Decreased pyoverdine production may be a mechanism for reducing the iron potentiation of oxygen toxicity. It is hypothesized that factors stimulating production of siderophores may increase the susceptibility of microorganisms to oxidative damage. In general, our research suggests new opportunities for predicting ecotoxicological outcomes based on understanding of molecular mechanisms and the effect of xenobiotics or stress factors on fundamentally important microbial processes.

Key words: cadmium; mercury; methyl viologen; oxidative stress; *Pseudomonas aeruginosa*; siderophore.

INTRODUCTION

It is generally accepted that our ability to make predictions about the ecological effect of pollutants is very limited (Moriarty 1988). Studies of the effects of xenobiotics or other stressors on critical physiological processes in organisms may be especially useful for the purpose of improving our ability to predict the ecological impact of pollutants and stressors. The assumption is that physiological function is the logical point of integration for ecotoxicological studies. Specifically, the impact of pollutants, or environmental stress, on physiology is relevant to population growth, interaction between species, relative fitness, indicator gene expression, and the interaction between organisms and the environment. Physiological measures that are fundamentally important and connected with specific environmental states are attractive candidates for study.

Microbes are obvious candidates for such studies because they play an essential role in ecological communities. Moreover, they are capable of modifying the environment by their metabolic processes. This power is manifest in microenvironments, or on a larger scale, as in geochemical change. In addition, certain bacteria

are model systems for the study of physiological processes. One example of the use of microbes for this approach is the study of phosphoenolpyruvate carboxylase regulation, which is motivated by the important role of this enzyme in the metabolism of (often limiting) dissolved organic matter in aquatic ecosystems by heterotrophic bacteria (Overbeck 1990). The effect of pollutants and stressors on critical aspects of microbial physiology is understudied with respect to the importance of microbes in the function of ecological communities. Such studies are valuable for the development of the field of ecotoxicology.

Iron acquisition is an essential physiological process for organisms. Iron is almost universally required for life, yet it is poorly soluble in the form of polyhydroxylated complexes at neutral pH (Neilands 1981). In some regions of the open ocean iron availability is the factor that limits phytoplankton population size (Kerr 1994). In order to meet this demand for iron, microbes, and other organisms use low molecular mass compounds, collectively called siderophores, to scavenge for iron (Guerinot 1994, Neilands 1995). Siderophores are important in relationship to the growth of aerobic and facultative anaerobic bacteria, fungal growth, plant growth, as well for their effects on the virulence of plant and human microbial diseases (Neilands 1981, Neilands and Leong 1986, Barton and Hemming 1993, Payne 1993).

Pseudomonas aeruginosa is associated with aquatic and other habitats, and is also known as an opportunistic pathogen of humans. This species belongs to a group of microorganisms, the fluorescent pseudomonads, that are widely distributed across a range of habitats. Among the fluorescent pseudomonads, *P. aeruginosa* is the taxon best known in terms of genetics and physiology. *P. aeruginosa* produces two siderophores; pyoverdine is predominant, and has a much higher affinity for iron than the other siderophore, which is called pyochelin. The structure of pyoverdine is presented in Briskot et al. (1989). Pyoverdine is a peptide containing eight amino acids: 1 L-arginine, 1 L-lysine, 2 L-threonines, 2 L- δ N-hydroxyornithines, and 2 D-serines. The octahedral coordination of Fe(III) is accomplished by two δ N-hydroxyornithines and an (IS)-5-amino-2,3-dihydro-8,9-dihydroxy-1H-pyrimido-[1,2-a]quinoline-1-carboxylic acid providing hydroxamate and catecholate donor oxygen atoms (Wendenbaum et al. 1983).

The present study addresses the question of whether exposure to xenobiotic stress factors results in a change in pyoverdine production by *P. aeruginosa*. Two of the metals employed in this study, cadmium and mercury, are significant environmental pollutants. In addition, experiments were conducted to determine if a nonmetal oxygen radical generator, methyl viologen (paraquat), could influence the production of pyoverdine. Paraquat is well established as a radical generator (Hassan and Fridovich 1979), and is used routinely to produce oxidative stress. Since iron is known to participate in the generation of oxygen radicals, exposure to this compound was motivated by the issue of iron management under conditions of oxidative stress.

MATERIALS AND METHODS

Pyoverdine measurement and bacterial growth

The fluorescent chromophore group of pyoverdine produces a characteristic pattern of excitation and emission (Meyer and Abdallah 1978). In the present study, a Perkin-Elmer (Oak Brook, Illinois) LS-5B luminescent spectrometer was used to qualitatively measure the abundance of pyoverdine by measuring fluorescence (excitation 405 nm and emission 450 nm), which is functionally equivalent to an established method of pyoverdine abundance determination (Meyer and Abdallah 1978, Cox and Adams 1985, Visca et al. 1992). Low concentration of iron stimulates pyoverdine production, and higher concentrations, such as 10 μ mol/L of supplemental iron, allows growth of *P. aeruginosa* with no siderophore production (Stintzi and Meyer 1994).

The *P. aeruginosa* strain used in this study was PAO1. Colonies were obtained by streak plating from -80°C 15% glycerol storage onto *Pseudomonas* Agar F (PAF) medium. For aqueous culture, cells were grown in standard succinate medium (SSM). SSM is a

low-iron medium that promotes siderophore production. Our experiments were designed to address the questions of whether added metals or an oxidative stress agent could stimulate or suppress the existing level of pyoverdine production in low iron medium. Growth in SSM was estimated by measurement of turbidity at an optical density of OD600 nm (Perkin-Elmer Spectrometer Lambda 3B). All solutions and media were prepared using double-distilled deionized water. Chemicals were from Sigma Chemical Company, St. Louis, Missouri unless otherwise stated.

Metal assays

In order to test the hypothesis that pyoverdine production by *P. aeruginosa* is influenced by the presence of heavy metals, dose response assays were conducted in which growth and pyoverdine production were monitored over time in samples taken from SSM culture. For these assays, PAO1 was inoculated from an overnight culture into 13 \times 100 mm borosilicate glass tubes (Fisher Scientific, Pittsburgh, Pennsylvania) containing SSM. All glassware used for cultures or assays was soaked in 0.1 mol/L HCl (Mallinckrodt Chemical, Paris, Kentucky) overnight to remove contaminating metals, followed by rinses with double-distilled water before autoclave sterilization. Overnight cultures were produced by inoculating a PAO1 colony from PAF medium into a 50-mL long-neck culture flask with 25 mL SSM. The growth period was \sim 16 h at 25°C with moderate shaking at 150 cycles/min.

After overnight growth, cells were centrifuged for 5 min at 59×10^3 m/s² at room temperature. The pellet was resuspended in sterile 0.85% NaCl. The centrifugation and resuspension steps were repeated. The pellet from the second centrifugation was resuspended in 0.85% NaCl to a standard final OD600 nm of 0.200. A 20- μ L aliquot of this bacterial suspension was used as the inoculum into each 13 \times 100 mm assay tube containing 3 mL of SSM. The control tubes contained 3 mL SSM with no added metals. The treatment tubes contained SSM with added metal chlorides (CdCl₂, HgCl₂, ZnCl₂). For cadmium and zinc, the experiments were conducted at final concentrations of 0.125, 0.25, 0.50, and 1.00 mmol/L. Solutions were prepared the day before inoculation of the assay tubes. The experiments with these metals were conducted four times. Mercury is highly toxic, and thus the concentrations employed (0.003–0.20 μ mol/L) were much lower than the other metals. Replicate experiments using mercury were conducted with an extensive series of concentrations for the purpose of bracketing the transition to conditions that reduced growth of PAO1 in SSM.

Growth (OD600) and the qualitative estimate of pyoverdine production derived from the measure of fluorescence, excitation at 405 nm (ex405) and emission at 450 nm (em450), were recorded at 8-h intervals during a 64-h incubation period. The experiment was

FIG. 1. Mean slope of pyoverdine produced (log excitation 405 nm, emission 450 nm/log OD600) as a function of added metal. *Pseudomonas aeruginosa* was continuously exposed to metals and sampled over time in standard succinate medium. The mean slope with no added metal was 6.85.

designed so that there were replicate tubes for each assay time point, and only a single growth and pyoverdine reading was taken from any one tube. Assay tubes were not reused for successive readings. Luminometer measurements (ex405em450) were typically obtained from a 1:1000 dilution, but ranging from dilutions of 1:100 to 1:10 000 depending on the level of fluorescence present in a sample.

Samples from SSM medium, and SSM medium with the high concentration of cadmium, were tested to determine how much of the characteristic pyoverdine fluorescence was quenched by addition of iron. The purpose was to estimate the proportion of residual fluorescent signal that could not be attributable to pyoverdine present in samples. The method was to dilute 64-h postinoculation samples to ~1000 luminometer units at ex405em450 and then add iron. Iron was added to a final concentration of 1.0 mmol/L, which has been shown in this study to quench almost all of the characteristic fluorescent signal from semipurified pyoverdine.

Semipurification of pyoverdine and metal quench tests

Pyoverdine was semipurified to determine if the metals we employed in assays quenched the fluorescent signal used to estimate pyoverdine abundance. This was accomplished in a manner similar to that described in Meyer and Abdallah (1978). Overnight growth of PAO1 was obtained as described for the metals assay. Bacterial cells were pelleted, washed, and diluted to a final OD600 of 0.200 in 0.85% NaCl. A 1.0-mL aliquot of the overnight culture was used as the inoculum into a 2-L Erlenmeyer flask containing 1.0 L of SSM. The culture in this flask was incubated at 25°C with moderate shaking for 72 h. Thereafter, the cells were pelleted by centrifugation at 127.5×10^3 m/s² for 10 min at 25°C. The supernatant was retained and concentrated by lyophilization. For lyophilization, 450 mL of culture supernatant was used to shell-coat the inside of bottles by rotation and freezing on the inside surface of a 1200-mL lyophilization bottle using a dry ice-ethanol bath applied to the exterior of the bottle. Bottles were at-

tached to a vacuum source and the contents freeze dried to a dry powder. The supernatant powder was resuspended in distilled water and solvent extracted as described by Meyer and Abdallah (1978).

Iron is known to quench pyoverdine fluorescence (Abdallah 1991). For the fluorescence quench assay, semipurified pyoverdine was measured before and after addition of different metals into solution. Semipurified pyoverdine was standardized with distilled water to ~1000 luminometer units (ex405em450) before addition of the test metals.

Methyl viologen exposure

In order to test the hypothesis that pyoverdine production is influenced by the presence of methyl viologen (paraquat), assays were conducted in which growth and pyoverdine production were monitored over time in SSM culture. Overnight cultures were grown, washed, and standardized as described for the metal assays. From a 100-mmol/L stock solution of methyl viologen, dilutions were made into SSM to final methyl viologen concentrations of 100 μ mol/L and 500 μ mol/L. Control tubes employed SSM without addition of methyl viologen. The tubes with SSM were inoculated with 20 μ L of standardized overnight culture of PAO1, as described for the metals assay. It is known that *P. aeruginosa* does not metabolize paraquat (Brown et al. 1995), and presumably metabolism of the compound does not play a role in these experiments. These assays were repeated a total of four times. The sampling intervals and total duration of incubation was longer than employed in the metal assays, because preliminary experiments indicated that it required longer to reach a reasonably consistent level of pyoverdine abundance.

RESULTS

Metal assays

The effects of cadmium and zinc on pyoverdine production are shown in Fig. 1. For each compound concentration, the average slope of the log of fluorescence (ex405em450) divided by log OD600 (pyoverdine production adjusted by growth) is presented for each concentration of a tested metal. The average slope for the controls, SSM without added metal, is 6.85. To show the effect of metals on the growth response, the average

Cadmium	0.018	0.017	0.013	0.005
Iron	0.027	0.027	0.023	0.014
Zinc	0.019	0.019	0.020	0.015

TABLE 2. Mean slope of the growth response and pyoverdine production by *Pseudomonas aeruginosa* exposed to mercury concentrations in standard succinate medium for 64 h.

Measure	HgCl ₂ concentration (μmol/L)							
	0	0.0031	0.0062	0.0125	0.025	0.050	0.100	0.200
Mean slope of growth (log OD600)	0.286	0.325	0.340	0.332	0.362	0.305	0.252	0.212
Mean slope of pyoverdine production (log excitation 405 nm, emission 450 nm/log OD600)	0.108	0.143	0.127	0.126	0.148	0.124	0.087	0.068

slope of the log of OD600 measurements is presented in Table 1.

In the present study, zinc did not have a substantial effect on growth or pyoverdine production, but cadmium was observed to affect both. The linear fit of the slope across a range of zinc concentrations is not significantly different from a slope of zero ($P = 0.3950$, $df = 1$). In contrast, cadmium acts to stimulate cell-density-adjusted pyoverdine production. In the case of cadmium, the linear fit of the slope of pyoverdine production is significant ($P < 0.0001$, $df = 1$), as is the fit to a quadratic slope ($P = 0.0075$, $df = 1$). The slope produced by 0.5 mmol/L Cd is 140% greater than the control and 1 mmol/L Cd is 300% greater than the control. The two higher concentrations of Cd stimulate pyoverdine production. This interpretation is supported by the statistical analysis, and inspection of the data suggests that the response is somewhat greater than loglinear (Fig. 1). There is evidence that the higher concentrations of cadmium are reducing the growth response (Table 1). Cadmium stimulates production of pyoverdine, but a question arises as to whether this is a nonspecific effect common to growth-inhibited (stressed) cells.

Table 2 presents the effect of mercury concentrations on growth and pyoverdine abundance. The mean slope values of log OD600 growth and log fluorescence at ex405em450 divided by log OD600 (pyoverdine production adjusted by growth) are shown for the 64-h growth period for each mercury concentration. In the concentration range from 0.003 to 0.05 μmol/L, the effect of mercury relative to the control appears to be a slight increase in growth and slight decrease of the measure of cell-density-adjusted pyoverdine abundance. The higher concentrations of mercury decrease growth, as indicated by Table 2 and supported by the fact that the 64-h OD600 was at least 10-fold lower in the presence of the highest concentration of mercury compared to control growth (data not shown). The measure of pyoverdine adjusted by cell density decreases at higher mercury concentrations (Table 2). Consequently, it is apparent that there is no universal association between stress (reduction of growth) and an increase in pyoverdine production.

Metal quench tests

The quench effect of iron and other metals was tested on semipure pyoverdine. At a final concentration of 1.0

mmol/L FeCl₃ the ex405em450 measure of semipure pyoverdine was quenched 99.8%. At the same concentration of iron using ex405em455, the fluorescence of semipure pyoverdine was quenched 99.7%. At a final concentration of 0.1 mmol/L FeCl₃ and ex405em450, the fluorescence of semipure pyoverdine was quenched 96.9%. At the same concentration of iron using ex405em455, the fluorescence of semipure pyoverdine was quenched 97.3%. At 0.1 mmol/L final concentration of iron, mercury quenched fluorescence 7.5%, cadmium 2%, and zinc <0.5%. Given the concentrations of mercury, cadmium, and zinc in solution after dilution of SSM cultures for fluorescence readings, it is unlikely that the metals significantly quenched fluorescence and thus impacted the measure of pyoverdine abundance in the experimental treatments. Moreover, there is no evidence that cadmium increases the fluorescent signal as an explanation for the increase in pyoverdine abundance when *P. aeruginosa* is exposed to cadmium in SSM.

Samples (64 h postinoculation) from the medium with the highest concentration of cadmium and control SSM were tested to determine how much of the characteristic pyoverdine fluorescence was quenched by addition of iron. At a final concentration of 1.0 mmol/L FeCl₃ and fluorescence readings at ex405em450, control sample fluorescence was quenched 94.4% and the fluorescence from the SSM with the highest concentration of cadmium was quenched 95.6%. At the same concentration of iron using ex405em455, control sample was quenched 88.4% and the fluorescence from the SSM with the highest concentration of cadmium was quenched 93.5%. Overall, the residual characteristic fluorescence that cannot be quenched by the addition of iron is small, suggesting that in this regard the measure of pyoverdine abundance is not subject to a bias sufficient to change the interpretation of the results. There is no indication that exposure to cadmium increases the proportion of this residual fluorescence.

Methyl viologen assay

Fig. 2 presents the pyoverdine production response of PAO1 cells to concentrations of methyl viologen. The mean variates are standardized to the control values to emphasize the pattern of response as a summary of four independent experiments. In each experiment, there was a significant reduction in the OD600-adjusted

FIG. 2. Mean fluorescence (excitation 405 nm, emission 450 nm) adjusted by cell density (OD600) as a measure of pyoverdine produced by *Pseudomonas aeruginosa* continuously exposed to methyl viologen in standard succinate medium. The means of the treatment variates are presented relative to the control; the control with no methyl viologen added was set at 1.0.

fluorescence. The level of support for significant treatment effects is $P = 0.0004$ (experiment 1), $P = 0.0495$ (experiment 2), $P = 0.0001$ (experiment 3), and $P = 0.0039$ (experiment 4). The data indicate that exposure to methyl viologen reduces pyoverdine production by PAO1 in SSM. Two earlier experiments (Hamer 1997) indicated that 100 µmol/L methyl viologen reduced fluorescence ~50% relative to controls, compared to 60% in the experiments shown in Fig. 2, and 500 µmol/L methyl viologen reduced fluorescence by 65%, compared to ~80% in the experiments shown in Fig. 2. From the earlier experiments it was observed that plated cells taken from the last time point of 500 µmol/L methyl viologen cultures showed lower levels of pyoverdine production than control PAO1 when reintroduced into SSM aqueous medium (Hamer 1997). This observation suggests that exposure of cells to paraquat selects for genetic variants that produce less pyoverdine. Strong selection is consistent with the reduction in cell density observed at early time points after inoculation. The apparent temporal oscillatory pattern of the treatment pyoverdine measurements presented in Fig. 2 are not a significant feature of the data, given the standard errors of the 48- and 96-h time points. Overall, the reduction of pyoverdine production in response to oxidative stress is interpretable in terms of an adaptive response that reduces the iron-mediated potentiation of oxygen toxicity.

DISCUSSION

We are the first to document a stimulatory effect of cadmium on pyoverdine production, and also the first to document that exposure to methyl viologen can decrease siderophore production. In this discussion, we argue that these effects may be general, and we predict a negative synergistic effect of cadmium and paraquat based on the effect of cadmium on the molecular mechanisms that control siderophore synthesis and iron potentiation of oxidative stress.

Aspects of the mechanism of microbial control of siderophore production may be highly conserved. First described in *Escherichia coli*, siderophore synthesis is negatively regulated by iron interaction with Fur a repressor protein (Bagg and Neilands 1987). Specifically, Fe(II) is the ligand that interacts with Fur, which then binds to an operator suppressing expression of siderophore synthesis genes. Fur and *fur* gene homologs have been characterized from *P. aeruginosa* (Prince et al. 1991, 1993) and other taxa (Guerinot 1994). The DNA sequences required for iron regulation may also be conserved (Neilands 1995, Rombel et al. 1995). Moreover, in *E. coli*, an enterobactin (siderophore) iron complex is taken into the cell by a specific receptor protein (Raymond 1994). Similarly, after pyoverdine forms a complex with iron, membrane-bound receptors participate in ferripyoverdine uptake (Meyer et al. 1990, Poole et al. 1993). In general, when iron is lim-

ited, gram-negative bacteria produce multiple outer membrane proteins as receptors which take up the ferri-siderophore complex, perhaps in a conserved manner by interaction with the TonB outer membrane protein (Guerinot 1994). As a result of mechanism conservation, data on the effects of xenobiotics and other environmental stressors on siderophore production in *P. aeruginosa* may extend to a range of microorganisms.

Various factors are known to influence siderophore production in fluorescent pseudomonads. As summarized by Meyer and Abdallah (1978), studies have shown that the nature of the carbon source in culture medium can influence production of pyoverdine-like pigment production. For *P. aeruginosa*, succinate was established as an optimal medium for production of this class of compounds (King et al. 1948) and this is likely to be a result of an iron requirement for the enzyme succino-dehydrogenase (Stinzi and Meyer 1994). Iron plays a pivotal role in controlling pyoverdine production by *P. aeruginosa* (Totter and Moseley 1953) and other microbes.

An additional layer of control of siderophore production has been documented in fluorescent pseudomonad taxa including *P. aeruginosa* (Leong et al. 1991, Cunliffe et al. 1995, Miyazaki et al. 1995). Totter and Moseley (1953) presented evidence that penicillin, but not streptomycin or chloromycetin, increased the production of pyoverdine-like pigment production in *P. aeruginosa*. Partially based on the work of Mergeay et al. (1978), Hofte et al. (1989) suggested that modulation of siderophore production was associated with a general stress response in various pseudomonads including *P. aeruginosa*. Antibiotics (ampicillin, tetracycline, and gentamycin) and metals (zinc and nickel) were implicated as stimulatory stressors. In contrast, the effect of mercury in our study does not support the hypothesis of increased pyoverdine production as a general stress response.

In our study, cadmium was found to stimulate pyoverdine abundance but zinc had no effect. The earlier assertion that cadmium inhibited pyoverdine production was based on a description of an interaction with cobalt resistance, but no data were presented to document this assertion (Mergeay et al. 1978). Our work, documenting a dose-dependent stimulation of pyoverdine abundance, supports the hypothesis that cadmium has a stimulating effect on pyoverdine production. Work on *E. coli* suggests that our results are correct. Specifically, in *E. coli* it has been shown that cadmium interacts with Fur protein thiols with high avidity, but the liganded repressor has reduced affinity for regulatory DNA sequences as determined by in vitro footprinting assays (Coy and Neilands 1991).

We did not observe an effect of zinc on pyoverdine production as might be expected by the results of Hofte et al. (1993, 1994). The activation by zinc (Hofte et al. 1993) is associated with a site-specific recombinase

gene (Hofte et al. 1994). Their studies investigated activation of siderophore expression in the presence of relatively high iron concentration, whereas our study was an investigation of the possible stimulatory effect of zinc when iron concentration is sufficiently low to allow pyoverdine production. Noteworthy in this regard is the data showing that 100 $\mu\text{mol/L}$ (or less) of zinc in low iron medium did not stimulate pyoverdine production by *P. aeruginosa* PAO1 (Visca et al. 1992). Alternatively, there may be differences between the 7NSK2 strain used by Hofte et al. (1993, 1994) and PAO1 used in our study and the work by Visca et al. (1992). Finally, differential outcomes may be derived from the use of plate assays (Hofte et al. 1993, 1994) vs. the aqueous culture assays used in the present study. In support of this possibility, a recombinase mutation continued to synthesize pyoverdine in LB broth supplemented with zinc, but not on an LB plate supplemented with zinc (Hofte et al. 1994).

Physiological measures can be used to detect and integrate the biological impact of stress factors. In spite of the intuitive appeal of physiological indicators, Bayne et al. (1979) has noted that general measures such as growth tend to obscure the identity of specific stress factors. Pyoverdine production is a specific physiological response that may provide some evidence about the nature of the stressor. However, it is increasingly apparent that the *P. aeruginosa* Fur regulatory system is complex, involving an array of coordinately regulated genes as well as various sigma factors and other global regulators (Tardat and Touati 1993, Cunliffe et al. 1995, Ochsner and Vasil 1996). Consequently, it is not clear to what degree a pyoverdine response could provide evidence about the specific identity of a stressor.

Iron potentiates oxygen toxicity, and virtually all organisms are expected to have evolved mechanisms for the purpose of iron management (Kaplan and O'Halloran 1996). Our study suggests that methyl viologen (paraquat) may act to suppress pyoverdine production. During *P. aeruginosa* culture, the reduction of oxygen in culture during stationary phase is associated with a burst of pyoverdine production under low iron conditions (Cox 1986) and an increase in potential in the cell (Hassan and Moody 1987). Methyl viologen is known to induce catalase and superoxide dismutase activities, presumably as oxygen stress protection mechanisms (Hassett et al. 1993, Brown et al. 1995). Fur mutations can have altered catalase and superoxide dismutase activities, and are defective in pyoverdine synthesis (Hassett et al. 1996). The sensitivity of these mutants to hydrogen peroxide and paraquat was greater than wild-type, and the suggestion was made that reduction in pyoverdine synthesis could be a contributing factor (Hassett et al. 1996). Perhaps in contrast, our results indicate that reduced pyoverdine production may be a consequence of exposure to paraquat, pre-

sumably to reduce the amount of iron assimilation and thereby reduce the potentiation of its toxic effects. Given the complexity of iron and oxygen regulation of gene expression in pseudomonads (Tardat and Touati 1993), it is plausible that under some circumstances pyoverdine expression could be decoupled from coordinate upregulation with catalase and superoxide dismutase activities.

The ecological consequences of maladaptive regulation of siderophore production is significant because iron management is a universal problem for organisms. For example, constitutive siderophore expression in *E. coli* results in increased sensitivity to near UV irradiation (Hoerter et al. 1996). In general, DNA-damaging oxygen radicals challenge the viability of microorganisms (Linn and Imlay 1987, Arrage et al. 1993).

Our research suggests new opportunities for predicting ecotoxicological outcomes based on the interaction of xenobiotics with molecular mechanisms that regulate key microbial processes. Specifically, based on the results of this study we are able to propose a hypothesis that relates pyoverdine production, cellular iron accumulation, and oxygen toxicity. The hypothesis could have general implications given the conserved mechanisms underlying control of siderophore synthesis. Importantly, we can make the detailed prediction that the effect of cadmium in stimulating pyoverdine production will predominate over the effect of paraquat in reducing pyoverdine production when *P. aeruginosa* is exposed simultaneously to both xenobiotics. In this scenario, the stimulatory effect of cadmium would be predominant because a diffusible factor, cadmium, is expected to reduce the functional availability of the Fur protein, which serves to repress gene expression for pyoverdine synthesis. Consequently when both cadmium and methyl viologen are present, the cell is hypothesized to take up an excess of iron by the vehicle of pyoverdine overproduction under conditions of oxidative stress due to the presence of methyl viologen. In this manner, the cell would amplify oxidative stress because iron potentiates oxygen toxicity. In general, we are arguing that a future avenue of ecotoxicological research should be to conduct mechanism-driven studies of synergistic effects of xenobiotics, or other stressors, based on fundamentally important features of microbial physiological processes.

This research was supported by the metallobiochemistry program at the University of Nebraska-Lincoln and by NSF-EPSCOR project 92-555225. We thank Professor Nielands for sharing his experience and insight, Ming-Hoi Wu for capable assistance, and Tony Joern for editorial contributions. In addition, we would like to thank Ronald Gorman and Kathie Helzer for diligent help in collecting data.
