Summary: Selenocysteine (Sec) tRNA occupies a prominent position in the expression of selenoproteins as it is essential for their synthesis and it provides the means by which selenium is co-translationally inserted into protein as the amino acid, Sec. Thus, Sec tRNA is regarded as the principle constituent in selenoprotein synthesis. Many features unique to this tRNA have been characterized over the years in mammals and other eukaryotes. In the last five years, the major advances have been in an elucidation of the different roles that the two major Sec tRNA isoforms play in selenoprotein biosynthesis and in Sec biosynthesis. One isoform appears to be responsible for the synthesis of selenoproteins that have roles in housekeeping functions and are less dependent on selenium status for their expression. The second isoform, that differs by only a single methyl group at the 2'-*O*-hydroxyl-ribosyl moiety at position 34 (designated Um34), appears to be responsible for the expression of selenoproteins that have roles in stress-related phenomena and are highly dependent on selenium for their expression. Several new observations regarding Sec biosynthesis, which occurs on its tRNA, have also been recently made. Other recent advances involving Sec tRNA have used this molecule as a tool for determining whether eukaryotes outside the animal kingdom contain the machinery dedicated for the insertion of Sec into protein. These recent findings are discussed in this chapter.

Introduction

Of all the tRNAs that have been identified and whose functions have been characterized, selenocysteine (Sec) tRNA is arguably the most fascinating. For example, it is responsible for the translation of an entire class of proteins, the selenoproteins. Unlike the other 20 amino acids in protein, Sec is biosynthesized on its tRNA. Furthermore, while the other 20 aminoacyl-tRNAs share a common elongation factor, eEF-2, Sec-tRNA has its own dedicated elongation factor, EFsec [1,2]. In addition, there are many other novel features in its primary and secondary structures, as well as in its transcriptional properties, which are unique only to this tRNA. As these unique characteristics have been reviewed in detail recently [3], they will not be further discussed herein. Of importance to our present discussion on Sec tRNA in mammals is that it exists as two isoforms that differ from each other by a single methyl group, 2'-*O*-methylribose, which is present at position 34, the wobble position of the anticodon. This methyl group is designated Um34 and its synthesis is a highly specialized event in the maturation of Sec tRNA (see below).

Sec tRNA has been detected in prokaryotes, eukaryotes and archaea, and therefore, is widespread in nature. However, while Sec tRNA has been characterized extensively in mammals and other animals [3], little is known about the properties, functions and distribution of this tRNA in other eukaryotic organisms. In fact, Sec tRNA, selenoproteins and/or the Sec protein insertion machinery have been reported thus far in only a handful of eukaryotes other than animals. The new data on the roles of the two mammalian isoforms in selenoprotein biosynthesis, Sec synthesis on its tRNA in mammalian cells and the occurrence of Sec tRNA in eukaryotes outside the animal kingdom are subjects of this review. For further information, the reader is referred to other, more extensive reviews on this subject [3,4].

Um34, a highly specialized event in mammalian Sec tRNA[Ser]Sec

Sec tRNA is designated as Sec tRNA[Ser]Sec, since it is first aminoacylated with serine and the biosynthesis of Sec occurs on the tRNA [3]. As noted above, there are two isoforms of Sec tRNA[Ser]Sec that differ from each other by the presence of Um34. Both isoforms have a highly modified base at position 34, 5-methoxycarbonylmethyluridine (mcm^{5}U), and they are thus designated mcm^{5}U and mcm^{5}Um. The synthesis of Um34, which is the last step in the maturation of Sec tRNA[Ser]Sec, has been described as a highly specialized event [3] since its addition 1) is dependent on the primary and tertiary structure of Sec tRNA[Ser]Sec, including the prior synthesis of all modified bases (the synthesis of other modified bases is not nearly as stringently dependent on these factors) [5], 2) is dependent upon selenium status [4], 3) alters secondary and tertiary structure [6], and 4) is responsible

for the synthesis of a subset of selenoproteins implicated in stress response [7,8]. The stress-related selenoproteins include glutathione peroxidase-1 and 3, SelR, SelT and likely SelW, and the dependence of this subclass of selenoproteins on mcm⁵Um is discussed in greater detail in Chapter 29 (see also [7,8]).

Interestingly, the expressions of stress-related selenoproteins, like the occurrence of mcm⁵Um, are dependent on selenium status. The lack of expression of this subclass of selenoproteins is a translational event due to the lack of Um34 on mcm⁵Um as the amount of mRNA encoding some of these selenoproteins is more than adequate for their expression following the reduction of mcm⁵Um due to selenium deficiency. However, the level of mRNA encoding some of these selenoproteins, e.g., GPx1 and SelW, is substantially reduced during selenium deficiency. This dependence of selenoprotein mRNA expression on selenium status was proposed to result from the mechanism of nonsense mediated decay (NMD), wherein the UGA Sec codon in selenoprotein genes is recognized as nonsense [9,10]. Different selenoprotein mRNAs manifest varying degrees of sensitivity to NMD and the reason for this is not clearly understood. In this regard, the sensitivity of mcm⁵Um to selenium status is of particular interest since the overall levels of the Sec tRNA[Ser]Sec population decrease significantly under conditions of selenium deficiency, while the amounts of mcm⁵U remain largely unchanged and may even be enriched (described in detail in [3]). A possible sequence of events during selenium deficiency is that Um34 synthesis is reduced which in turn prevents the expression of several stress-related selenoproteins and the corresponding mRNAs manifest varying degrees of sensitivity to NMD.

The dependence of a subclass of proteins, and in this case, stress-related selenoproteins, on a methyl group for recoding a nonsense codon (UGA) to generate their expression is, to our knowledge, an unprecedented observation in translation. To elucidate the means by which Um34 is responsible for the expression of a subset of selenoproteins, we examined various parameters of selenoprotein mRNAs such as nucleotide context of the UGA codon, position of the UGA codon in the open reading frame and the class of the Sec insertion sequence element (located in the 3' untranslated region of selenoprotein mRNAs and required for the incorporation of Sec into protein [11]), but none of these features revealed any clear pattern that would explain this phenomenon (reviewed in [3]). The precise mechanism of how UGA is recoded by mcm⁵Um in stress-related selenoprotein mRNAs resulting in their expression is currently under investigation.

Um34 methylase
Although the methylase that synthesizes Um34 on Sec tRNA[Ser]Sec has not been identified, a protein described by Ding and Grabowski, designated SECp43 [12], may have a role in Um34 synthesis [13]. These investigators

reported that SECp43 existed in a complex with a 48 kDa protein and Sec tRNA[Ser]Sec in HeLa cell extracts. A 48 kDa protein, designated soluble liver antigen (SLA), had been earlier characterized as it co-precipitated with Sec tRNA[Ser]Sec after being targeted by antibodies in patients with an autoimmune chronic hepatitis [14]. We recently found that the 48 kDa protein which formed a complex with SECp43 and Sec tRNA[Ser]Sec is indeed SLA [13,15]. Furthermore, we found that knockdown of SECp43 in mammalian cells using RNAi technology reduced the formation of Um34 [13] suggesting that it is involved in Um34 synthesis. Further studies are required to determine if SECp43 is associated with methylase function and how it is precisely involved in Um34 synthesis. However, we investigated additional parameters of SECp43 and SLA [13]. The targeted removal of either SECp43 or SLA affected the binding of the other to Sec tRNA[Ser]Sec, even though tRNA[Ser]Sec attachment was most affected when SLA was the targeted member of the complex. In addition, we observed that SECp43 is located primarily in the nucleus, while SLA occurs in the cytoplasm. Cotransfection of both proteins resulted in the nuclear translocation of SLA. This result suggested that SECp43 may also serve as a chaperone for shuttling SLA and Sec tRNA[Ser]Sec between different cellular compartments. SLA likely has a role in the biosynthesis of Sec as discussed below.

Sec Biosynthesis
Sec is distinctive from the other 20 amino acids in protein in that Sec biosynthesis occurs on its tRNA [3,5]. Although asparagine, glutamine and cysteine biosynthesis can occur on tRNA[Asn], tRNA[Gln] [16] and tRNA[Cys] [17], respectively, this means of synthesizing these amino acids appears to be restricted to only a few life forms. However, Sec apparently is synthesized on its tRNA in all organisms that encode the Sec-protein insertion machinery which, as noted above, is widespread in nature. Serine is attached to Sec tRNA[Ser]Sec by seryl-tRNA synthetase, and thus, the identity elements for recognizing this tRNA are for serine and not Sec. The identity elements in Sec tRNA[Ser]Sec are located in the discriminator base and the long extra arm which are essential to its aminoacylation, even though the acceptor, TψC and D stems also have roles in the identity process (reviewed in [3,5]). Following the aminoacylation of Sec tRNA[Ser]Sec, the serine moiety serves as the backbone for the synthesis of Sec on its tRNA.

   The enzyme that carries out the synthesis of Sec utilizing the serine moiety on seryl-tRNA[Ser]Sec is designated Sec synthase and its identity and mechanism of action has been thoroughly characterized in bacteria (Chapter 2). However, in mammals, a homolog of the bacterial enzyme is absent and the overall biosynthesis of Sec on its tRNA has not been established. In 1970, a kinase activity that phosphorylated a minor species of seryl-tRNA to form phosphoseryl-tRNA was observed in rooster liver [18] and a minor

seryl-tRNA that decoded UGA was reported in bovine, rabbit and chicken livers [19]. The phosphoseryl-tRNA and the seryl-tRNA that decoded UGA were subsequently found to be Sec tRNA[Ser]Sec [20], but the kinase activity remained elusive until only recently. A gene for mammalian phosphoseryl-tRNA[Ser]Sec kinase (*pstk*) was identified using a comparative genomics approach by searching completely sequenced archaeal genomes for a kinase-like protein with the pattern of occurrence similar to that of known components of the Sec insertion machinery [21]. A gene corresponding to a potential mouse *pstk* was cloned, the gene product (PSTK) expressed and characterized. PSTK specifically phosphorylated the seryl moiety on seryl-tRNA[Ser]Sec confirming that indeed the seryl-tRNA[Ser]Sec kinase had been correctly identified. A search of proteins with homology to mammalian PSTK revealed homologs in *Drosophila, Caenorhabditis elegans, Methanopyrus kandleri* and *Methanococcus jannaschii*. These observations suggest that the function of PSTK has been conserved in archaea and eukaryotes that synthesize selenoproteins, but this function is absent in bacteria and eukaryotes, e.g., plants and yeast, that do not synthesize selenoproteins.

Since PSTK has been highly conserved in evolution, it must have an important role in selenoprotein biosynthesis and/or its regulation [21,22]. A similar reaction as that which may occur in Sec biosynthesis in mammals has been observed in archaea wherein cysteine biosynthesis on tRNA[Cys] takes place by the initial aminoacylation of the tRNA with phosphoserine and subsequently converting the phosphoserine moiety to cysteine by a pyridoxal phosphate-containing Cys synthase [17]. This pathway serves as an excellent model providing further evidence that phosphoseryl-tRNA[Ser]Sec is indeed an intermediate in the biosynthesis of Sec (see also [22]).

A mammalian Sec synthase distinct from that described in bacteria (Chapter 2) could then act upon phosphoseryl-tRNA[Ser]Sec in removing the phosphate group and accepting the active selenium donor to make selenocysteyl-tRNA[Ser]Sec. Interestingly, a candidate Sec synthase is SLA (see above for further characterization of SLA). This protein was identified several years ago [14], and has more recently been characterized as an important member of the Sec biosynthesis and protein insertion machinery [13,15] (see also Chapter 8).

The active form of selenium that is donated to the intermediate in the biosynthesis of Sec has been characterized in bacteria as monoselenophosphate, which is synthesized from selenide and ATP by selenophosphate synthetase [23]. Although the active selenium donor has not been characterized in eukaryotes, two selenophosphate synthetase genes, designated *Sps1* and *Sps2*, have been detected in mammals [24-26]. SPS2, the gene product of *Sps2*, is a selenoprotein which suggests that it may be involved in the autoregulation of its own biosynthesis [24]. When the

activated form of selenium is donated to the intermediate, which might be a product of phosphoseryl-tRNA[Ser]Sec catalyzed by SLA, the biosynthesis of Sec on tRNA[Ser]Sec would be complete and the Sec moiety then poised for insertion into the nascent selenopeptide (see Chapter 8). If this hypothesis is correct, it may be anticipated that the mechanism of Sec is synthesized on the tRNA will be resolved in the near future.

Occurrence and evolution of Sec tRNA[Ser]Sec and its insertion machinery
In 1989, the synthesis of Sec on its tRNA was reported simultaneously in bacteria [27] and mammalian cells [28]. These observations unequivocally demonstrated that Sec was the 21st amino acid in the genetic code. Even though earlier studies had suggested that Sec was the 21st amino acid [29-31], when it was recognized that Sec biosynthesis occurred on its tRNA, the possibility that an intermediate, e.g., phosphoserine [20], might first be incorporated as the 21st amino acid and then changed posttranslationally to Sec had to be ruled out (see discussion in [28]).

Evidence was subsequently provided that the Sec tRNA[Ser]Sec gene (*trsp*) was universal in the animal kingdom [32] and *trsp* was found in numerous species of prokaryotes [33]. The occurrence of selenoproteins and the Sec protein insertion machinery was subsequently reported in archaea (see [34] and references therein), but only recently were this machinery [35] and Sec tRNA[Ser]Sec [36-38] observed in eukaryotes outside the animal kingdom. Initially, the Sec incorporation machinery and at least 10 selenoproteins [35] were found in *Chlamydomonas*, a green alga and a member of the plant kingdom.

Since Sec tRNA[Ser]Sec is a convenient marker for identifying the presence of the Sec protein insertion machinery in an organism, attention was focused on a means of demonstrating the occurrence of this nucleic acid in different eukaryotes. Initially, we devised a relatively simple procedure for partially purifying and then sequencing Sec tRNA[Ser]Sec by reverse transcription (RT)-PCR and sequenced the Sec tRNA from *Chlamydomonas* [36]. A computational Sec tRNA genomic analysis program for detecting *trsp* in partially or completely sequenced genomes was also developed (A.V. Lobanov, G. V. Kryukov and V.N. Gladyshev, unpublished data). The latter procedure in combination with isolating and sequencing the gene product by RT-PCR provided an easy and direct method for assessing whether organisms encode the machinery for incorporating Sec into protein. Sec tRNA[Ser]Sec was identified in two model organisms, *Dictyostelium discoideum* and *Tetrahymena thermophila* [37]. The sole termination codon is *T. thermophila* is UGA (see [37] and references therein) and the demonstration that this organism also encodes Sec tRNA suggests that its only stop codon has a shared function. It is therefore important to note that *T. thermophila* does indeed utilize its Sec tRNA for making selenoproteins as

its genome encodes selenoprotein genes (A.V. Lobanov and V.N. Gladyshev, unpublished data). *trsp* was also recently identified in various species of *Plasmodium* [38,39] and in *Toxoplasma gondii* [38].

Sec tRNAs are the longest tRNAs known in either eukaryotes, archaea or prokaryotes. Prokaryotes are the longest found tRNAs thus far with some exceeding 100 bases in length [34]. All known animal Sec tRNAs[Ser]Sec are 90 bases in length as are those from *Chlamydomonas* [36] and *Tetrahymena* [37]. *trsp* in *Toxoplasma gondii* is 87 bases long [38] which indicates its gene product is 90 bases in length as the CCA terminus is added posttranslationally in all tRNAs. *Dictyostelium* Sec tRNA is 91 nucleotides [37] and those from various species of *Plasmodium* are 93 nucleotides [38,39]. The extra base in *Dictyostelium* Sec tRNA[Ser]Sec occurs in the D-stem, while the extra three bases in *Plasmodium* occur in the long extra arm. The clover leaf model of mammalian Sec tRNA[Ser]Sec and that of *Dictyostelium* are shown in Figure 1.

Sec tRNA[Ser]Sec

Figure 1. Cloverleaf model of mammalian (A) and *Dictyostelium* (B) Sec tRNA[Ser]Sec. The secondary structure of the tRNA is shown in a 9/4 based paired form (i.e., 9 base pairs in the acceptor stem and 4 base pairs in the T-stem).

It is amazing that so much energy has been invested in developing a highly sophisticated system during evolution for the insertion of single amino acid, Sec, into protein. Most of the known functions of Sec in protein are involved in redox reactions and thus the driving force for evolving the Sec protein incorporation machinery most likely was to utilize the unique chemical properties of the selenium atom in Sec. Under reducing environment of the cell, Sec is ionized as its pKa (~5.5) is below physiological pH and it is a better participant in certain redox reactions than Cys. The pKa of Cys is 8.3, therefore, many cysteines are protonated under physiological conditions.

The dependence of different organisms on selenoproteins for survival varies widely within the three life kingdoms, eubacteria, archaea and eukaryotes. Some organisms, such as yeasts and higher plants, do not utilize selenoproteins at all, while others, such as higher vertebrates, are dependent on selenoproteins for their survival (see [3,34] and references therein). Other organisms, such as many prokaryotes, encode the Sec protein insertion machinery, but its occurrence often is not essential to their survival, although there must be some selective advantage for them to maintain this machinery. These observations raise important unresolved questions in selenium biology. For example, why, once such a sophisticated system evolved for utilizing the unique properties of selenium, don't all organisms take advantage of selenoproteins in cellular metabolism, or alternatively, why have some organisms lost the ability to make selenoproteins?

Although there is likely no single solution to this question, a better understanding of those organisms that do and do not make selenoproteins will most certainly shed light on this enigma. As Sec tRNAs provide a readily identifiable marker for the presence of the Sec protein insertion machinery, and the computational and sequencing techniques described above are so readily applicable to identifying Sec tRNAs, focusing on the occurrence of *trsp* and/or Sec tRNA will provide a means of assessing how widespread the use of Sec is in nature.
