It has been accepted for inclusion in Faculty Publications, Department of Psychology by an authorized administrator of DigitalCommons@University of Nebraska - Lincoln.
Hypertension affects some 25% of adults in the United States and is a major risk factor for stroke, myocardial infarction, and renal insufficiency. Epidemiologic studies indicate that between 30% and 50% of the population variation in diastolic and systolic blood pressure (BP) is attributable to genetic factors; specific genes associated with BP or hypertension have been difficult to identify. Rare Mendelian forms of hypertension result in distinctive abnormalities of renal sodium handling. Although the specific genetic disorders associated with these hypertensions are rare in the general hypertensive population, the principle that genetic variation affecting renal tubular sodium transport and pressure-natriuresis may underlie some fraction of essential hypertension suggests the possibility that common alleles for other genes involved in renal sodium handling could contribute to hypertension.

One of the most important regulators of sodium balance is renal dopamine. In normotensive subjects, the action of locally released dopamine is responsible for more than 50% of incremental sodium excretion during states of moderate sodium excess. In essential hypertension the effect of dopamine on renal sodium excretion is blunted. Most studies investigating the role of dopamine receptors in the control of renal sodium excretion and BP have focused on the dopamine-1 (D1) receptor, and both a D1 receptor gene polymorphism (A-48G) and a variant in the G protein-coupled receptor kinase 4 gene (GRK4gA142V) have been found to be associated with hypertension. Others have suggested that diminished...
renal dopamine production may play a role. Recent evidence points to a potential role for dopamine-2-like (D2) receptors in BP regulation. The site mediating the BP effects of both D1 and D2 receptors may well be the kidney, where D1 receptors inhibit renal tubular basolateral Na-K ATPase and luminal Na-H antiport and decrease tubular sodium reabsorption, whereas activation of D2 receptors stimulates Na-K ATPase. Thus, either the proposed defect in D1-inhibited or enhancement of D2-stimulated sodium reabsorption could promote hypertension.

Dopamine-4 (D4) receptors (along with dopamine-3 receptors) are part of the D2-like family of dopamine receptors. It has been observed that D4 knockout mice show an increase in fear, unconditioned anxiety, and sensitivity to alcohol. Cardiovascular profiles of these mice have not been reported. The most intensively studied D4 receptor polymorphism is a 48 bp repeat located in exon 3 of the D4 receptor gene (DRD4). This variant codes for a 16-amino acid sequence located in the third intracellular loop of the D4 receptor protein, a region that is thought to interact with G-proteins and influence intracellular levels of cAMP. The number of repeats at the DRD4 site varies from 2 to 10, but in populations of white ethnicity the 4 and 7 repeat lengths are the most common. Despite much investigation, it is still not clear what functional effect, if any, this polymorphism produces. Extensive study has been given to DRD4 in human behavioral genetics. The presence of a long allele (7, 8, or 10 repeat) at the DRD4 site has been strongly associated with attention deficit hyperactivity disorder. In addition, there are conflicting, but predominantly negative, reports concerning the association of the D4 receptor long allele and both increased scores for the personality trait Novelty Seeking and alcohol dependence. However, no studies investigating the role of D4 variants in BP have been reported. In this study we explored the association between DRD4 and BP; we also examined putative associations between DRD4 and both personality traits and alcohol use.

**Methods and Materials**

**Study Population**

The present analysis includes 479 female and 385 male subjects from 286 families participating in the National Heart, Lung, and Blood Institute Family Blood Pressure Program at the site in Tecumseh, MI. Of the subjects, 99% were of non-Hispanic white ethnicity. Family eligibility in this study was dependent on the availability of a proband between 25 and 40 years old with systolic BP in the upper 15% of the BP distribution in earlier rounds of examinations and a sibling willing to participate. Because we used BP as a quantitative phenotype in this study, treatment with antihypertensive medications excluded subjects from this analysis. In addition, subjects with elevated serum creatinine (> 1.5 mg %), diabetes mellitus, pregnancy, or serious medical illness were excluded. When available, parents and additional siblings of included probands were studied irrespective of BP. All participants read and signed an informed consent document approved by the University of Michigan Institutional Review Board for Human Subject Research.

**Genotyping**

The D4 receptor variant was amplified using primers D4-42 (5'-AGGACCTCTATGGGTTTG-3') and D4-3 (5'-GCGACTACGTGGTCTACTCG-3'). A PTC 100 thermal cycler (MJ Research, Watertown, MA) was used for DNA amplification. Amplification reactions were performed in a total volume of 20 μL, containing approximately 50 ng of genomic template, 1 μmol/L of each primer, 200 μmol/L dNTP, 2 μL 10X Opti-Prime Buffer #6 (Stratagene, La Jolla, CA), and 1 U of Taq polymerase. The polymerase chain reaction cycling conditions consisted of an initial denaturation for 2 min at 94°C followed by 35 cycles of 94°C for 1 min, 60°C for 2 min, and 72°C for 2 min, and a final extension at 72°C for 4 min. The polymerase chain reaction products were electrophoresed on a 2% agarose gel and visualized under ultraviolet light using the GelStar nucleic acid gel stain (BioWhittaker Molecular Applications, Rockland, ME).

In accordance with previous studies, subjects were grouped on the basis of the presence of a long allele (7, 8, or 10 repeats).

**Blood Pressure Assessment**

Blood pressure measurements were made with a standardized protocol by a single observer (LG) previously trained and certified in BP measurement technique. Two manual measurements were obtained for each subject with a standard mercury manometer, and the average systolic and diastolic BP were used in this study. Pulse pressure is the difference between systolic and diastolic pressure.

**Questionnaire**

Personality traits were assessed through the NEO Personality Inventory (NEO-PI). This inventory, consisting of 181 questions, assesses subjects on five global personality domains and breaks down three of these domains (Neuroticism, Extraversion, and Agreeableness) into six facets each. The NEO-PI is a well established inventory constructed through factor analytic strategies and provides high test-retest reliability and longitudinal stability. A weighted Novelty Seeking score was calculated from NEO-PI domain scores using the formula described by Benjamin et al.

Data necessary to establish diagnoses of alcohol abuse and dependence were not collected in this sample. However, subjects were asked: “Have you ever regularly consumed alcohol in your life?” The presence of association between D4 receptor genotypes and subjects’ response to this question were also explored.
Statistical Analysis

The presence of association was determined using the QTDT Program version 2.1 (available at http://www.sph.umich.edu/statgen/abecasis/QTDT/). QTDT was used to fit a variance components model to account for familial resemblance because of kinship and linkage. However, rather than modeling allelic effects based on allelic transmission, we tested the overall additive genetic effect of each polymorphism. The presence of a statistical interaction between D4 receptor genotypes and age for diastolic and systolic BP was determined through a general linear model in SPSS 10.0 (SPSS Inc., Chicago, IL). Familial resemblance was not considered in testing for interactions. A concern in this type of study is the potential presence of population stratification that could result in false association. To assess whether the reported results were caused by stratification, STRUCTURE, a program designed to infer population structure using genotypes from numerous unlinked markers as genomic controls, was implemented.

Results

We determined DRD4 genotypes at the D4 receptor repeat polymorphism for 864 subjects examined at the Tecumseh, MI, site of the National Heart, Lung, and Blood Institute Family Blood Pressure Program. The allele frequencies (adjusted for familial correlation) were consistent with previously reported frequencies for white populations (Table 1).

In an analysis controlling for familial correlations, we found an association between the presence of a D4 receptor long allele and higher systolic (P = .031) and diastolic BP (P = .034) (Table 2) but not pulse pressure (P = .179) (Table 2). In addition, there were significant interactions between D4 receptor genotype for age and systolic BP (P = .009) and age and pulse pressure (P = .0002). Figure 1 shows the interaction of age and mean systolic BP. For diastolic BP, there was no evidence of an interaction between genotype and age (P = .824).

In this study, subjects with the long allele had a higher frequency of self-reported regular alcohol use at some point during their lives compared with self-reported life-time abstainers (P = .008). We could not distinguish between alcohol use and abuse using our available data. There was no correlation between reported lifetime history of alcohol use and systolic BP, diastolic BP, or pulse pressure in either male or female subjects in this sample. The D4 receptor variants showed no associations with any of the five NEO-PI personality traits or with a weighted Novelty Seeking personality trait (Table 2).

Weak evidence for clustering into two groups was found (P = .02) (B. Thiel and N.J. Schork, unpublished observations, 2003). However, there were no significant differences in D4 receptor allele frequency, systolic or diastolic BP, alcohol use, or any of the personality traits between the two clusters. Thus these reported results are unlikely to be the product of population stratification.

Discussion

The results of this study indicate that the D4 receptor length polymorphism in exon 3 accounts for a small but significant proportion of the population variation in both systolic and diastolic BP in our sample of individuals of white ethnicity. In addition, we find evidence that the effect of D4 receptor genotype on systolic BP and pulse pressure is strongest in subjects >60 years of age.

The mechanisms mediating an association between the D4 length polymorphism and high BP are unknown, as there is limited information available concerning the potential role of D4 receptors in cardiovascular or renal function. Clozapine, an “atypical” antipsychotic agent with a relatively selective D4 affinity, has been reported to cause both hypotension and hypertension as well as substantial increases in heart rate, perhaps through stimulation of D4 receptors expressed in the heart. Experimental studies have identified several renal physiologic effects associated with D4 receptor activation. In the cortical collecting tubule, D4 receptors antagonize the effects of V₂ vasopressin receptors and aldosterone, thereby decreasing sodium and water reabsorption. There is also a reported interaction between D4 and angiotensin II type 1 receptors, which could affect renal sodium reabsorption. Along with proximal and distal tubules, D4 receptors are found prejunctionally in renal nerves that are widely distributed in periadventitial tissues of segmental, arcuate, interlobar, interlobular, afferent, and efferent arterioles and the glomerular capillary tuft. The expression of D4 receptors on juxtaglomerular cell suggests a possible role in the control of renin release, although a D4 receptor mutation model in mice does not demonstrate alteration of renal function or circulating renin levels.

The interaction observed between D4 receptor genotypes and age is of interest because systolic and pulse pressures rise continuously from middle age onward. It seems likely that the effects of genes affecting the level of BP differ over time, either because they are active during a critical period in the evolution of hypertension or because they contribute to age-related target organ effects caused by hypertension.

If D4 receptor genotypes affect renal sodium handling, they may contribute to the increasing prevalence of salt sensitivity of BP with the aging process.
In addition to the relationship to BP, we also found an association between D4 receptor long alleles and a self-reported history of regular alcohol use. Most studies that have investigated D4 receptor variants and alcohol have focused on alcohol dependence or abuse. Although some studies have found an association between D4 receptor long alleles and increased incidence or severity of these traits, most findings have been negative. Given our results, it may be fruitful to investigate the role of D4 receptor in the initiation of alcohol use rather than the escalation of alcohol use to the level of abuse and dependence. There is no association in this sample between D4 receptor and personality traits, a finding consistent with the results of two recent meta-analyses.

In summary, our findings support a role for a common D4 polymorphism in the control of systolic BP in individuals >60 years of age. Investigation of the actions of D4 receptors in cardiovascular-renal physiology may yield insight into a mechanism of hypertension in human beings.
