ABSTRACT

Forage management practices influence the quantity and quality of forage available to grazing cattle. The objectives of this experiment were to determine the effects of prescribed fire or herbicides on the density of forbs, the production and nutritive value of the herbage, and the performance of beef steers grazing Yellow bluestem [Bothriochloa ischaemum (L.) Keng var. ischaemum (Hack.) Celarier and Harlan] pastures. The experiment was conducted in northwestern Oklahoma from 1998 through 2000, and the untreated pastures (control) were not burned or sprayed. The prescribed-fire treatment (PFT) occurred annually between March 27 and April 10. The herbicide treatment (HT) consisted of an annual application of 0.9 kg of 2,4-dichlorophenoxyacetic acid and 2.8 g of metsulfuron methyl per hectare. Compared with the control, forb densities were or tended to be decreased (P < 0.13) in PFT and HT pastures only in May and June of 1998; forb densities were not affected (P ≥ 0.45) in later months or years. Dry matter production of Yellow bluestem in August was not affected (P ≥ 0.10) by treatment, but CP concentration and in vitro OM disappearance were greater (P ≤ 0.05) in herbage collected early in the grazing season from PFT pastures than in that from control and HT pastures. Over the 92-d grazing period that started May 30 (initial stocking rate, 1.93 steers/ha), ADG and BW gain per hectare did not differ (P ≥ 0.74) among treatments. Forb control with prescribed fire or the herbicides used in this experiment did not improve the performance of beef cattle grazing Yellow bluestem pastures even though prescribed fire improved forage quality early in the grazing season.

Key words: Bothriochloa ischaemum, cattle, forb, herbicide, prescribed fire

INTRODUCTION

Yellow bluestem [Bothriochloa ischaemum (L.) Keng var. ischaemum (Hack.) Celarier and Harlan; aka, Old World bluestem] is an important forage for grazing livestock worldwide. This grass is native to Eurasia from the equator north to the 56° latitude, and it has been naturalized to North America (Celarier and Harlan, 1958). Prescribed fire or herbicide applications are tools for managing Yellow bluestem pastures on the Southern Plains of the United States. The 2 main objectives of burning this grass in the spring are to remove standing dead herbage and decrease weed populations because livestock performance is commonly believed to increase. The primary objective of herbicide application to Yellow bluestem is to decrease weed and brush populations and increase DM production by the grasses, which then can be converted into livestock gains (Fuhlendorf et al., 2009). In Oklahoma, 30% of Yellow bluestem pastures are treated annually with a broadleaf-selective herbicide to

increase forage production and, sub-
sequently, livestock production (New,
1997). Studies of herbicide applica-
tion typically focus on the production
of weeds and grasses on small scales
and rarely address effects on livestock
performance (Thilenius et al., 1975;
Fuhlendorf et al., 2009). The applica-
tion of prescribed fire or herbicides
is often based on the appearance of
standing herbage mass of dormant
forage or annual weed densities in the
early spring rather than on the result-
ing quantitative effects on production
characteristics.

Prescribed fire for native rangelands
dominated by warm-season grasses
has been shown to increase livestock
production (Anderson et al., 1970;
McCollum et al., 1992), and it is often
assumed this response is applicable to
monocultures of introduced warm-sea-
son grasses such as Yellow bluestem.
Nonetheless, Berg (1993) reported
that prescribed fire decreased forage
production of Yellow bluestem and
recommended further study on its
effects on livestock performance. The
overall effect of prescribed fire relative
to livestock performance has not been
documented for Yellow bluestem. The
objectives of this experiment were to

determine the effects of prescribed fire
or herbicides on the density and pro-
duction of forbs, the production and
nutritive value of the herbage, and
the performance of beef cattle steers
grazing Yellow bluestem pastures.

MATERIALS AND METHODS

Site and Experimental Design

The study was conducted from 1998
through 2000 at the USDA, ARS,
Southern Plains Experimental Range
(lat 36° 35′ N, long 99° 35′ W; eleva-
tion 630 m) near Fort Supply, Okla-
homa. All experimental procedures
were approved by the Southern Plains
Range Research Station Animal Care
and Use Committee.

The regional climate is continental
with an average annual precipita-
tion of 576 mm, with 72% normally
falling during the April to September
growing season. Average monthly
mean temperatures are 2.3°C in Janu-
ary and 28°C in July. Minimum and
maximum recorded temperatures are
−28°C and 45°C, respectively. Soils
of the experimental pastures were
primarily fine sandy loams of the
Grandfield series (Typic Haplustepts)
and Hardeman and Grandmore series

(Typic Haplustalfs; NRCS, 2008).
The pastures used in this experiment
supported monocultures of 3 differ-
ent cultivars of Yellow bluestem: 3 of
Plains (Taliaferro et al., 1972), 3 of
WW-Spar (Dewald et al., 1985), and
3 of WW-Iron Master (Dewald et al.,
1988). All pastures were more than 10
yr old, previous weed control practices
were unknown, and pastures ranged in
size from 1.7 to 3.6 ha.

The pasture treatments consisted
of a control that was not burned or
sprayed with a herbicide (control), a
burned treatment that was burned
between March 27 and April 10
each year (prescribed-fire treatment,
PFT), and an herbicide treatment
applied between May 20 and 30 an-
nually (**HT**). Ambient temperatures
during burning were 15 to 21°C, rela-
tive humidity was 25 to 35%, wind
speeds were 5.3 to 6.7 m/s, and fires
were ignited downwind with drip
torches. The herbicide application was
a mixture of 0.9 kg of 2,4-dichlorophe-
noxyactic acid and 2.8 g of metsul-
furon methyl per hectare. Herbicides
were tank mixed with water and
applied with a tractor-mounted boom
sprayer. The total volume of water
and herbicide applied was 93.5 L/
ha. All pastures were fertilized with
56 kg/ha of N from urea (45-0-0) and
39 kg/ha of P from triple-phosphate
(0-46-0) fertilizers broadcast as prills
on approximately April 15 annually.
Treatments were blocked by variety of
Yellow bluestem. For each treatment,
2 blocks (n = 6 pastures total; 3 of
WW-Iron Master and 3 of WW-Spar)
were used in 1998 and 3 blocks (n = 9
pastures total; 3 of WW-Iron Master,
3 of WW-Spar, and 3 of Plains) were
used in 1999 and 2000.

Cattle Measurements

All pastures were grazed by cross-
bred yearling beef steers (initial BW
= 258 ± 20 kg; British × Continen-
tal) at a stocking density of 1.93
steers/ha. As recommended by Berg
(1993), grazing started on May 30
and ended on August 30, resulting
in a 92-d grazing period. Experimen-
tal herds consisted of 3 to 7 steers,
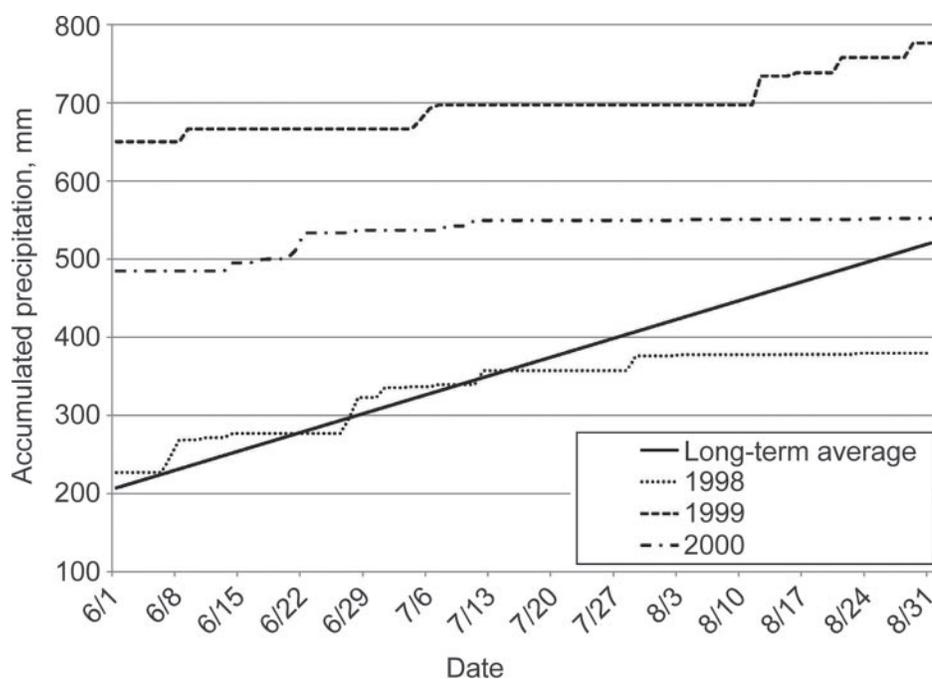

Figure 1. Accumulated precipitation for 1998, 1999, and 2000 between June 1 and
August 31 at the Southern Plains Experimental Range near Ft. Supply, Oklahoma.

depending on pasture size. Because of limited precipitation in 1998 (Figure 1), stocking density was decreased from 1.93 to 1.29 steers/ha after the first 30 d of grazing. Steers were not given any supplemental feed during the experiment but had ad libitum access to 23-kg blocks of plain salt. Steer BW were collected in the morning after fasting overnight (17 h) without feed or water on May 30, June 30, July 28, and August 30, annually, and BW were recorded.

Herbage Measurements

Each May, 5 exclosures (4.9 × 4.9 m) consisting of wire panels with a 15-cm mesh were placed randomly in each pasture before grazing; exclosures were moved to new locations annually. In mid August, herbage production by Yellow bluestem and forbs was determined by hand clipping 2 quadrats (0.29 × 0.61 m) to the ground level inside each exclosure, and residual herbage was determined by hand clipping 2 quadrats outside each exclosure. Herbage samples were dried at 60°C for 5 d before weighing. Densities of all forbs were counted with 0.25-m^2 quadrats (40/pasture) in May, early June (approximately 3 wk after herbicide application), and in mid August. Forb density data were converted to plants per square meter by multiplying the raw data by 4. Herbage mass samples for chemical composition analysis were collected on each cattle weigh date by paced transects and clipping current growth for the year (20 to 30 g DM) of Yellow bluestem plants at 6 points in each pasture. Herbage mass samples were amalgamated within pasture, oven dried at 60°C for 72 h, uniformly ground to pass a 1-mm screen, and analyzed for total N (Bremner and Breitenbeck, 1983) and in vitro OM disappearance (**IVOMD**; Tilley and Terry, 1963 as modified by White et al., 1981). Nitrogen concentration was multiplied by 6.25 to estimate CP. The IVOMD:CP ratio was calculated by dividing the percentage of IVOMD by the percentage of CP on a DM

basis as described by Gunter et al. (1995a).

Statistical Analysis

Pasture means of forb densities, CP and IVOMD concentrations in the herbage mass, and the IVOMD:CP ratio were analyzed with an ANOVA using the Mixed Models procedure in SAS (SAS Institute Inc., Cary, NC) as a split-plot in time (month). The fixed effects in the model were treatment, years, months, and their interactions; the random effect was grass variety. Steer BW, ADG by period and the entire grazing season, total BW gain, standing herbage mass (inside and outside the exclosures), and BW gain per hectare were analyzed with an ANOVA using the Mixed Models procedure in SAS. The fixed effects in the model for animal performance variables and standing herbage mass were treatment, years, and their interaction; the random effect was grass variety. In all analyses, year was considered a fixed effect because of the small number of years sampled. If a significant *F*-test was detected ($P \leq 0.05$), least squares means were separated using predicted differences (Steel and Torrie, 1980).

RESULTS AND DISCUSSION

Climate and Precipitation

Winter precipitation at the Southern Plains Experimental Range weather station (2.0 km southwest of pastures) was above the long-term average (207 mm; January to May from 1988 to 1997) for all years (227, 650, and 485 mm for 1998, 1999, and 2000, respectively; Figure 1). Precipitation from June 1 to August 31, the primary production period for Yellow bluestem, was quite different among years. In 1998, pre-grazing-season (winter) precipitation was near normal; however, precipitation during the grazing season (June 1 through August 31) was 48% (153 mm) of the long-term average (317 mm). Because of the ability of Yellow bluestem to respond quickly to precipitation

(Philipp et al., 2007), adequate precipitation at the end of June and early July of 1998 stimulated new forage growth (Figure 1). In contrast, during 1999 and 2000, pre-grazing-season precipitation was 314% (650 mm) and 221% (485 mm), respectively, of the long-term average (207 mm). June 1 to August 31 precipitation was below average (232 mm) in 1999 (126 mm) and 2000 (94 mm). However, because of the above-average precipitation the previous winters of 1999 and 2000, soil moisture seemed to remain sufficient for forage production.

Pasture Measurements

Forb density interacted ($P < 0.01$) by treatments, months, and years. In May 1998, forb density in the control pastures (18 plants/m^2) differed ($P < 0.01$) from that in the HT (22.6 plants/m^2) and PFT (6.2 plants/m^2) pastures. The HT treatment was not applied until May 20 in 1998, which was 17 d after the forb densities for May had been counted (May 3); however, the PFT treatment had been applied on April 10. In May of 1999 and 2000, forb densities did not differ ($P > 0.05$) among the treatments. Also, forb densities in May of 1998 were less ($P < 0.01$) than in 1999 (control = 2.0, PFT = 1.2, HT = 1.1 plants/m^2) or 2000 (control = 0.6, PFT = 0.5, HT = 0.8 plants/m^2). In June 1998, forb densities in control pastures (3.5 plant/m^2) were greater ($P \leq 0.02$) than those in HT pastures (0.01 plant/m^2), with those in PFT pastures (1.2 plant/m^2) being intermediate ($P \geq 0.13$). No differences ($P \geq 0.67$) were noted in forb densities among treatments or years (range, <0.05–1.4 plants/m^2; data not presented).

The seasonal decrease in forb densities cannot be attributed to the dry conditions noted during 1998 because forbs also declined in 1999 and 2000, when precipitation was more favorable. Forbs were identified by species; they were dominated by annual species (87% of all forbs). Major forbs included horseweed [*Conyza canadensis* (L.) Cronq.], Texas toadflax [*Linaria*

canadensis (L.) Dum.], clasping Venus' looking-glass [*Triodanis perfoliata* (L.) Nieuw.], and carpetweed [*Mollugo verticillata* (L.)]. This seasonal decrease in forbs in Yellow bluestem pastures is not surprising because Bodine et al. (2001) reported that forbs were present in measurable quantities only during May in unburned plots of Plains Yellow bluestem but were almost devoid by late summer. This seasonal response is evidence of the competitive ability of well-managed Yellow bluestem to capture nutrients from the soil, putting competing forbs at a disadvantage (Springer, 2007). Furthermore, Gunter et al. (1995b) reported that annual forbs in a Plains Yellow bluestem pasture located near Bessie, Oklahoma (located 145 km south of our experimental site), managed with no burning or herbicides decreased from 19% of the total stand in May to trace levels (<0.5%) by October. In 2 experiments examining broadleaf weed control on mixed-grass or tallgrass prairies, forb populations were more strongly correlated with year than with herbicide application (Fuhlendorf et al., 2002, 2009). Thus, results of the present and previous experiments suggest little long-term benefits of herbicide use for controlling broadleaf weeds in Yellow bluestem pastures because the majority of weeds are annuals and will decrease because of antagonism from the Yellow bluestem.

Production of DM by Yellow bluestem pastures inside the exclosures, where grazing was excluded, did not differ among treatments (P = 0.89; control = 6,340, PFT = 6,130, HT = 6,370 kg/ha; SE = 424). Yellow bluestem DM production, where grazing occurred, outside the exclosures, also did not differ ($P \geq 0.11$; control = 4,970, PFT = 5,210, HT = 3,700 kg/ha; SE = 710). The herbage DM production of Yellow bluestems was affected ($P < 0.01$) by years, both inside and outside the exclosures. In 1998, standing herbage DM production of Yellow bluestems inside the exclosures (4,290 kg/ha) was less (P < 0.01) and did not differ (P = 0.23) outside the exclosure (3,450 kg/ha)

compared with 1999 (6,710 and 4,380 kg/ha, respectively); however, quantities in 2000 (7,840 and 6,050 kg/ha, respectively) were both greater ($P <$ 0.04) than in 1999.

The amount of standing herbage DM in the grazed areas estimated in mid August indicates that herbage DM allowance was likely not limiting herbage DMI; the herbage DM allowance was always greater than 1,344 kg/steer as suggested by Johnstone-Wallace and Kennedy (1944) as the point at which allowance limits DMI. Regarding the HT treatment, Fuhlendorf et al. (2009) also found no effect of herbicide treatments on the DM production by perennial warm-season grasses in mixed-grass prairie in western Oklahoma. For the PFT treatment, the current results differ from those reported by Berg (1993), who noted that burning decreased forage DM production of Iron Master Yellow bluestem an average of 16% (range, 6 to 30%). One major difference between these 2 experiments is that the study by Berg (1993) was conducted on loamy soils compared with the sandy loam soils of the current experimental location. In addition, Berg (1993) selected an earlier average date to apply fire (March 24) in 3 of the 4 yr of the experiment at Woodward, Oklahoma (581 m elevation); in the last year, Berg (1993) burned on April 6, and herbage DM production did not differ compared with nonburned sites. In an experiment in north-central Oklahoma (293 m elevation), annual DM production of Plains Yellow bluestem was not affected by prescribed fire (April 4; Bodine et al., 2001) when applied later in the spring as in the last year of the experiment by Berg (1993). Research conducted on tallgrass prairie has shown that early spring burning decreases herbage DM production compared with unburned prairies, whereas burning in late spring has no effect on herbage DM production (Anderson et al., 1970; Towne and Owensby, 1984). Some researchers have suggested that the effect of prescribed fire and its timing on herbage DM production is related to soil texture and water-

holding capacity. Soils with a greater water-holding capacity may be less susceptible to decreased herbage DM production when burning is applied in the early spring (Engle and Bidwell, 2001). In the present experiment, the water-holding capacities of the Grandfield and Grandmore soils were both 3.3 cm in the top 25 cm (NRCS, 2008); the Carey and Quinlan soils at the site used by Berg (1993) had water-holding capacities that were 39% (4.5 cm) and 26% (4.1 cm) greater in the top 25 cm than those at our site (NRCS, 2008). Hence, the suggestion that the effect on herbage DM production is related to water-holding capacity of the soil does not seem to hold true in this instance (Engle and Bidwell, 2001).

Herbage Quality

Crude protein concentration, IVOMD, and the ratio of IVOMD to CP concentrations in forage samples interacted ($P < 0.01$) among treatments, months, and years. However, data are compared among treatments and years within months in the following discussions.

In May of all years, CP concentration in the PFT pastures was greater ($P < 0.01$) than that in the control pastures, but the HT pastures did not differ ($P \geq 0.17$) from the control pastures (Table 1). Also, CP concentration in May of 1998 was less ($P <$ 0.01) than that in 1999 for all treatments, and in 2000 the CP concentration was intermediate ($P \leq 0.05$) to 1998 and 1999. The HT pastures in May 2000 did not differ ($P = 0.23$) from those in May 1999. In June, CP concentration of PFT or HT pastures did not differ ($P \geq 0.08$) from that of the control pasture during any year. For the control and HT pastures in June, CP concentration was lower (P < 0.05) in 1998 than in 1999 or 2000, but no differences ($P > 0.05$) were noted among years in the PFT pastures. In July and August of 1998, CP concentration was greater ($P \leq 0.05$) in PFT and HT pastures than in the control pastures, but CP concentrations did not differ ($P > 0.28$) among

[1]Control = not burned or sprayed with herbicides; PFT = annual prescribed fire between March 27 and April 10; and HT = annual application of a mixture of 0.9 kg/ha of 2,4-dichlorophenoxyacetic acid and 2.8 g/ha of metsulfuron methyl between May 20 and 30.

[2]n = 2/treatment in 1998, n = 3/treatment in 1999 and 2000.

treatments in 1999 or 2000. For all treatments in July and August, CP concentration was greater ($P > 0.05$) in 1998 than in 1999 or 2000.

In our experiment, herbage CP concentration was only consistently improved by the PFT treatment in the May to June period (Table 1). The use of prescribed fire on native rangeland has consistently increased CP concentration of cattle diets in only the early portion of the grazing season (Angell et al., 1986). The increased CP concentration noted in herbage produced after a prescribed fire in our experiment and other reports is likely the result of increased N mineralization and decreased nitrogenase activity in the soil (Hobbs and Shimel, 1983) because almost all the herbage N is volatilized during the fire (Redmann, 1991). From May to August the CP concentration generally decreased. Other research has reported this downward trend in CP concentra-

tion from May to August with Yellow bluestems (Berg, 1993; Gunter et al., 1995b; Philipp et al., 2005). The exception to this trend was in July and August of 1998 because rainfall was more abundant than in 1999 and 2000 (Figure 1). After precipitation or irrigation, Yellow bluestem continues DM accumulation later in the growing season compared with native grasses (Hodges and Bidwell, 1993; Gunter et al., 1995b; Philipp et al., 2007), which results in sharp increases in herbage CP concentration (Gunter et al., 1995b).

During 1998, IVOMD was greater ($P \leq 0.02$) in PFT pastures than in control pastures; however, the IVOMD in HT pastures did not differ ($P \geq 0.06$) from that in control pastures (Table 2). In June and July of 1999, HT had a greater ($P < 0.04$) IVOMD than did PFT or control pastures. In vitro OM disappearance did not differ ($P \geq 0.23$) among treatments in Au-

gust 1999 or all of 2000. In May 1999, the control and HT pastures had greater ($P < 0.01$) IVOMD than in 1998 or 2000, but the PFT pastures in 2000 had a lower ($P < 0.03$) IVOMD than in 1998 or 1999. In July and August across treatments, IVOMD was greater ($P < 0.05$) in 1998 than in 1999 or 2000.

Prescribed fire has generally increased in vitro digestibility of herbage in the early parts of the grazing season, but the benefits generally diminish as the season advances (Angell et al., 1986). Although Bodine et al. (2001) did not measure IVOMD, they reported that burning Plains Yellow bluestem did not affect the leaf:stem ratio of the standing herbage mass. Because the leaves of grasses in the *Bothriochloa* genus have greater digestibility than the stems (White and Dewald, 1988, 1996), the lack of change in the leaf:stem ratio with prescribed fire suggests a minimal effect of burning on its digestibility. Only a single experiment was located that reported the effect of herbicide application on the ruminally digestible energy values of the dietary herbage. Thilenius et al. (1975) reported that total VFA concentrations in the ruminal fluid of cattle grazing subalpine rangeland in Wyoming did not differ between pastures sprayed with 0.9 kg of 2,4-dichlorophenoxyacetic acid per hectare (10% forbs) and nonsprayed pastures (79% forbs), suggesting no difference in ruminal VFA production. In the present study, IVOMD generally decreased with the advancing grazing season, which is in agreement with other reports (White and Dewald, 1996; Gunter et al., 1997; Philipp et al., 2005). The increase noted for IVOMD in July 1998 was associated with increased precipitation in June (Figure 1). Gunter et al. (1995b) reported a similar increase in IVOMD for esophageal masticate samples collected from Plains Yellow bluestem after significant precipitation occurred 2 wk before sampling in late summer.

In May and June, no differences ($P > 0.11$) were detected among treatments or years (Table 3). In July, forages samples collected in 1998

from the control pastures indicated a greater ($P < 0.05$) IVOMD:CP ratio compared with the PFT and HT pastures; no differences ($P > 0.05$) were detected in IVOMD:CP ratios among treatments in July of 1999 or 2000. In August, forage samples collected in 1998 and 2000 from the control pastures had a greater ($P < 0.05$) IVOMD:CP ratio than did samples from the PFT and HT pastures, but no differences ($P > 0.05$) were detected in 1999. In July and August, forage samples collected in 1999 or 2000 had a greater ($P < 0.05$) IVOMD:CP ratio than did samples collected in 1998.

A ratio of IVOMD:CP between 4.0 and 4.5 indicates a balance of ruminal-available N to ruminal-available energy in cattle diets (Hogan and Weston, 1970; Gunter et al., 1995a). Based on this premise, when this ratio is greater than 4.5, a supplement high in ruminally degradable N would be the most efficacious choice for stimulating microbial protein production in the rumen. In contrast, when dietary N is not limiting (ratio <4.5), a high-starch or digestible fiber supplement would be more beneficial (Nocek and Russell, 1988). The ratio of IVOMD:CP was 5.0 or greater for all sampling dates. Based on the suggestion of Gunter et al. (1995a), a supplement high in ruminally degradable N, such as cottonseed (*Gossypium hirsutum*) meal, would have increased ADG during the experiment, especially after June 1. Moore et al. (1999) examined the ratio of IVOMD:CP in forage-based diets with a wide range of qualities and various supplement types offered (protein and energy type supplements). These researchers found that when the IVOMD:CP ratio was greater than 7, supplementation generally increased forage DMI (Moore et al., 1999). With the recommendation of Gunter et al. (1995a) for ruminally degradable N supplementation when the ratio of IVOMD:CP is greater than 4.5, their model predicts an increase in microbial protein production in the rumen. For the herbage samples collected in May, no IVOMD:CP ratios were greater than 7 (Table 3). With sampling periods after May, 73% of the ratios were 7 or greater. Supplementation of cattle grazing Yellow bluestem pastures with a ruminally degradable N source during late June through August would probably increase forage DMI compared with nonsupplemented cattle; supplementation would probably be expressed in increased ADG.

Cattle Measurements

Year and treatment did not ($P \geq 0.09$) interact for steer BW or ADG between June 30 and August 31, total BW gain, and BW gain per hectare (Table 4); however, ADG for the period from May 30 to June 30 was affected ($P = 0.03$) by the interaction between treatment and year (Figure 2). In 1998 and 1999, ADG from May 30 to June 30 did not differ ($P > 0.10$) by treatment, but in 2000, steers grazing the control and HT pastures had greater ($P < 0.04$) ADG than did steers grazing the PFT pastures. Steers grazing the control pastures had a greater ($P < 0.01$) ADG in June in 2000 than in 1998 or 1999. For all treatments in 1998, steers had lower ($P < 0.01$) ADG than in 1999 and 2000. Average daily gain was not affected by treatment ($P \geq 0.67$) for the periods of July 1 to July 28, July 29 to August 30, and May 30 to August 30 (Table 4). Steer BW was not affected ($P \geq 0.57$) by treatment within any month; steer BW did differ by year ($P \leq 0.05$; data not shown) because of differences in initial starting BW. Likewise, ADG in the periods from July 1 to August 30 or from May 30 to August 30, total BW gain, and BW gain per hectare were not affected ($P \geq 0.74$) by treatment. However, ADG from May 30 to August 30 and BW gain per hectare did

ing to have a positive effect on steer performance in our experiment. First, standing dead vegetation was insufficient to augment any potential advantage of burning. Second, grazing may not have started early enough in the spring to fully capture any potential benefits of burning because these effects are typically greatest in the early growing season (Angell et al., 1986; McCollum et al., 1992). In the area of Oklahoma where this experiment was conducted, stocking of native mixed-grass pastures normally occurs 3 to 4 wk before Yellow bluestem is recommended to be stocked (McIlvain and Shoop, 1962; Shoop and McIlvain, 1971; Berg, 1993). If this second reason is correct, burning of Yellow bluestem would have had limited potential to increase steer BW gain because grazing could not have started more than 7 to 14 d earlier if the initial stocking densities were to be maintained over the entire season. As discussed previously, using prescribed fire earlier in the spring to initiate grazing at an earlier date may potentially result in decreased total herbage DM production (Berg, 1993). In experiments conducted in Woodward, Oklahoma, production by Iron Master Yellow bluestem and Cauca-

differ ($P \leq 0.03$) by year (data not shown) because of differences associated with the random effects of years. Years did not differ for ADG from July 1 to July 28 or in total BW gain per hectare ($P \geq 0.23$). Because BW gain per steer and stocking densities did not differ among treatments, BW gain per hectare also was not affected ($P = 0.78$) by treatment (Table 4).

Others have reported ADG ranging from 0.6 to 1.3 kg for steers grazing Yellow bluestem pastures (Berg and Sims, 1995; Teague et al., 1996; Ackerman et al., 2001), which is similar to the range in ADG of 0.95 to 1.09 kg recorded in the present experiment. The burning of native grasslands dominated by warm-season grasses has generally increased steer BW gains, especially early in the growing season (Anderson et al., 1970; Angell et al., 1986; McCollum et al., 1992). There are at least 2 possible explanations for the failure of burn-

Table 4. Least squares means of BW and performance of steers grazing Yellow bluestem pastures as affected by prescribed fire or herbicide treatment[1] in northwestern Oklahoma

Item and month	Control	PFT	HT	SE[2]	*P*-value

[1]Control = not burned or sprayed with herbicides; PFT = annual prescribed fire between March 27 and April 10; and HT = annual application of a mixture of 0.9 kg/ha of 2,4-dichlorophenoxyacetic acid and 2.8 g/ha of metsulfuron methyl between May 20 and 30.

[2]n = 8/treatment.

[3]May BW was used a covariate ($P < 0.01$).
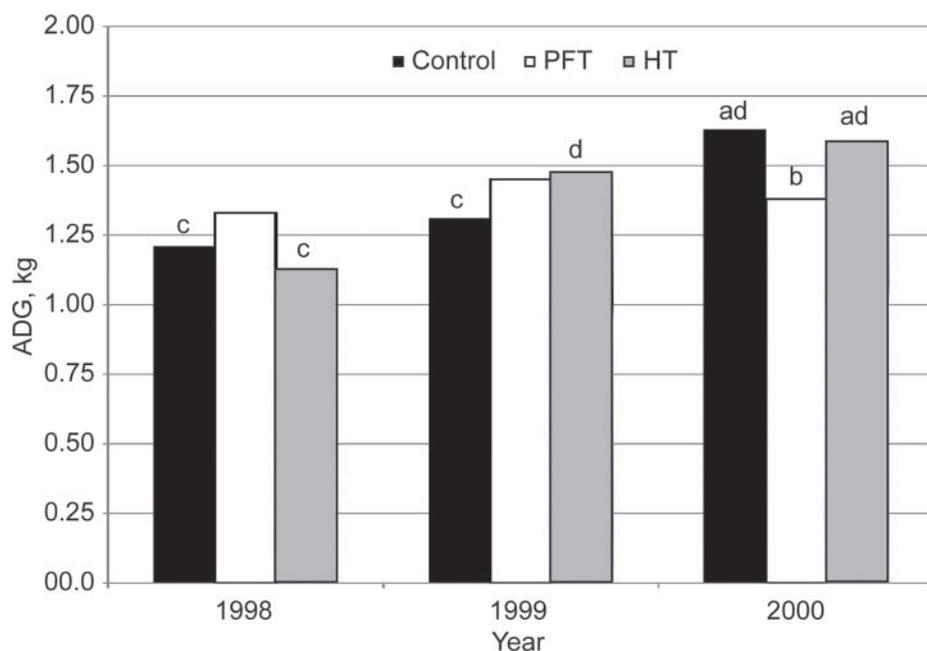

Figure 2. Average daily gain by steers grazing Yellow bluestem pastures between May 30 and June 30 in 1998 (n = 2/treatment), 1999 (n = 3/treatment), and 2000 (n = 3/treatment) at the Southern Plains Experimental Range near Ft. Supply, Oklahoma. Treatments were as follows: Control = not burned or sprayed with herbicides, PFT = annual prescribed fire between March 27 and April 10, and HT = annual application of a mixture of 0.9 kg/ha of 2,4-dichlorophenoxyacetic acid and 2.8 g/ha of metsulfuron methyl between May 20 and 30. [a,b]Least squares means within years that do not have common letters differ ($P < 0.05$). [c,d]Least squares means within treatments that do not have common letters differ ($P < 0.05$).

sian bluestem [*Bothriochloa caucasica* (Trin.) C.E. Hubb.] was only between 1,150 and 1,280 kg/ha of leaf material during May (White and Dewald, 1996). This rate of leaf production during May, assuming a 50% forage wastage that is normally associated with continuous stocking, would not produce enough herbage per hectare to carry 260-kg steers at the 1.93 steers/ha stocking rate. Hence, starting the grazing season earlier on Yellow bluestem at the present stocking rate does not seem to be a practical option.

The response of livestock performance to forb control with herbicides is seldom reported. As in our experiment, livestock performance was not influenced by herbicide application on rangelands like those found in western Oklahoma (Fuhlendorf et al., 2009) or in Wyoming (Thilenius et al., 1975). Forbs were a greater proportion of the vegetation in these rangeland studies than in ours (23% of canopy cover in western Oklahoma,

75% of the herbage DM production in Wyoming). For cattle to benefit from herbicide application, 1 of 2 things probably needs to occur. First, the forbs controlled by the herbicide application should not to be plants used by the cattle. Research with cattle grazing Yellow bluestem pasture has shown that between 5 and 49% of the total dietary DM can be from forbs (Gunter et al., 1995b). Chemical analysis of the forbs has shown them to be potential sources of high-quality dietary herbage. Gunter et al. (1995b) reported that Russian thistle (*Salsola iberica*) can contain between 27 and 28% CP, which can contribute significantly to diet quality at the percentages of the diet reported. Second, if forbs are removed from nonequilibrium grasslands, the remaining grass will need to replace forbs in the diets through increased DM production. Weed control in grass communities with herbicides on small plots has increased the production of grasses (Morrow and McCarthy, 1976; Rice

and Stritzke, 1989). The extrapolation of small-plot data to grasslands violates our understanding of scaling in grassland ecosystems (Fuhlendorf and Smeins, 1996, 1999). Pastures for small-plot studies (smaller scale) are normally selected based on their uniformity to minimize plot-to-plot variation. In larger-scale research, treatments are applied over areas with a high degree of temporal variation across multi-landscapes. Large-scale research on nonequilibrium rangeland has indicated no increase in grass DM production as a result of herbicide treatment (Fuhlendorf et al., 2002, 2009), and this is also evidenced by our results from annual herbage DM estimates inside and outside the exclosures (Table 2).

IMPLICATIONS

The PFT and HT treatments had similar effects on forbs in this experiment; there was no value of forb control regarding animal performance. Yellow bluestem is competitive with forbs as evidenced by the seasonal decrease in forb densities in the control treatment. If forb populations are dominated by annuals, little treatment carryover can be expected from year to year. This fact decreases the value of forb-control treatments even further because treatment costs cannot be annualized over years. Berg (1993) recommended that prescribed fire not be used with Yellow bluestem unless there was a need to remove excessive dormant forage or to control a specific plant because he observed that burning decreased forage production. Results from our experiment suggest that annual prescribed fire or herbicide application is not beneficial to the management of Yellow bluestem. Appropriate fertilization and proper grazing management seem to be the most effective methods to manage Yellow bluestem.
