($P < .05$) feeding system x finishing diet interaction was observed for feed conversion. Feed conversion was improved in both PG treatment groups irrespective of diet when compared with AL. Additionally, feed efficiency of the PG/WCGF treatment group was improved versus all other treatments.

Cumulative performance and carcass data are presented in Table 3. All steers were fed for 161 days. There was a significant ($P < .05$) feeding system x finishing diet interaction for DMI related to the magnitude of the difference between each AL control group and its PG counterpart. When feeding DRC, PG reduced intake by 3.43 lb/d. However, the difference when feeding WCGF was 5.29 lb/d. The relationship for the total amount of feed consumed throughout the trial responded similarly. There were significant main effects of both feeding system ($P < .05$) and finishing diet ($P < .10$) for daily gain. Feeding WCGF increased daily gain while the

PG feeding system reduced daily gain.

There was a significant ($P < .05$) feeding system x finishing diet interaction for feed conversion similar to that observed for both dry matter intake and total feed consumed. When feeding DRC, PG improved feed conversion 2.4% and the two feeding systems were not statistically different. However, when feeding WCGF, efficiency was improved 11.9% in the PG feeding system.

There were main effects of both feeding system ($P < .05$) and finishing diet ($P < .10$) for hot carcass weight. Feeding WCGF increased hot carcass weight while the PG feeding system decreased hot carcass weight. The PG feeding system significantly reduced ($P < .05$) marbling score. There were significant main effects for both feeding system ($P < .05$) and finishing diet ($P < .10$) for 12th rib fat thickness. Feeding WCGF increased fat thickness while the PG feeding system reduced fat thickness.

Net return was increased ($P < .10$) by feeding WCGF and was reduced ($P < .05$) by the PG feeding system. Similarly, cost of gain was reduced ($P < .10$) when feeding WCGF and increased ($P < .05$) by the PG feeding system.

These data indicate that including a programmed gain phase in the finishing system reduced both daily gain and profitability. Regardless of diet, feeding cattle ad libitum was strongly favored in this trial when compared to the programmed gain finishing system. However, there may be differences in the observed efficiency response to programmed gain finishing systems among finishing diets that differ in composition.

Economic Evaluation of Corn Processing for Finishing Cattle

Rob Cooper
Todd Milton
Terry Klopfenstein
Dick Clark¹

Economics of high-moisture corn are highly dependent on the discount at which it is purchased to dry corn. Economics of steam-flaked corn are attractive at corn prices common in Nebraska.

value of dry-rolled corn, respectively. Estimated costs of corn processing (\$/ton) ranged from \$1.44 to \$1.60 for dry-rolled corn, \$1.98 to \$2.34 for high-moisture corn, and \$6.79 to \$7.16 for steam-flaked corn. Economics of high-moisture corn are dependent on the discount at which it is purchased to dry corn. Economics of steam-flaked corn are dependent on corn price, but appear attractive at prices common in Nebraska.

odology, cost and effectiveness in increasing value. Dry rolling, high moisture and steam flaking are the most common forms of corn processing in feedyards today. High moisture and steam flaking are more costly than dry rolling, but an increase in cattle performance may offset these costs. Objectives of this evaluation were to determine economic return of high-moisture and steam-flaked corn relative to dry-rolled corn in diets for finishing cattle.

Introduction

The cattle feeding industry in the United States commonly processes corn to some degree before it is incorporated into a ration and delivered to the animal. The goal of most processing methods is to increase starch availability of corn, thereby increasing its value to the animal. Corn processing can vary in meth-

Procedure

Performance

Ninety crossbred yearling steers (612 lb) were used in a completely randomized design with a 3 x 5 factorial treatment structure to evaluate effect of corn processing on performance of

(Continued on next page)

Summary

A finishing trial was conducted to determine performance of steers fed dry-rolled, high-moisture and steam-flaked corn-based diets. High-moisture corn and steam-flaked corn were determined to have 100% and 108% the

finishing cattle. Steers were randomly assigned to one of three finishing diets (Table 1) which were based on dry-rolled (DRC), high-moisture (HMC), or steam-flaked corn (SFC). Within each diet, steers were randomly assigned to one of five levels of urea (0, .5, 1.0, 1.5, or 2.0% of dietary DM).

Steers were individually fed using Calan electronic gates. Steers were offered their respective finishing diet on day 1 at 1.8% of body weight (DM basis). Feed offered then was increased .5 lb per day (DM basis) until steers were ad libitum (approximately 21 days).

Steers were weighed initially on three consecutive days after being limit-fed at 2.0% of body weight for five days in order to minimize differences in gut fill. Steers were implanted with Synovex C on day 1, reimplanted with Synovex Plus on day 67, and fed for a total of 167 days. Final weights were calculated using hot carcass weights adjusted to a common dress (63%). Data were analyzed using Mixed procedure of SAS. Least square means were separated using the Least Significance Difference method.

Economics

Economics of corn processing are dependent on both value change in corn as well as cost of processing. Information regarding both of these factors is discussed below. It is important to note that many assumptions are made in this economic evaluation. Although assumptions are believed accurate given available information, readers are encouraged to substitute values that more accurately reflect their own situation.

Value of processing. The best indicator of value change due to corn processing is cattle performance. For this discussion, it will be assumed that a change in feed conversion is directly related to a change in value of corn. Therefore, if feed/gain is improved by 10% by a processing method, the corn has 10% more value. This approach has limitations, but seems conservative and straightforward. This approach is conservative because corn does not comprise 100% of the diet. All changes in value in this discussion are relative to DRC because it is the simplest form of

Table 1. Composition of finishing diets (% of DM).

Ingredient	Diet ^a

^aDRC = dry-rolled corn, HMC = high-moisture corn, SFC = steam-flaked corn.

^bHigh-moisture was rolled at harvest and stored in covered concrete bunker and was 29% moisture and 46% soluble protein at time of trial.

^cSteam-flaked corn was processed to 29 lb/bushel flake weight at a commercial feedyard facility and hauled to research feedlot on weekly basis.

^dAll diets supplemented to contain a minimum of .7% Ca, .28% P, .6% K, and .15% S (DM basis). All diets contained 27 g/ton Rumensin and 10 g/ton Tylan (DM basis).

processing in the performance data.

Costs of processing. There are four primary costs associated with corn processing: initial costs of equipment, electricity, natural gas and diesel fuel. Available literature was reviewed to estimate these costs.

Initial costs of equipment are difficult to estimate because they can be extremely variable depending on the type of system and available resources. Costs reported in literature (Schake et al. 1981. Energy and economic evaluation of corn and sorghum processing. Texas Agricultural Experiment Station, pp. 1-12) were used for this evaluation; however, readers should substitute costs which more accurately reflect their own situation. In the report mentioned above, initial equipment costs (\$/head feedyard capacity) associated with DRC, HMC, and SFC for 5,000 and 20,000 head feedyards were estimated (Table 2). No attempt was made to update these costs for inflation because we were unsure how much costs on a \$/head basis have changed. For this discussion, equipment was depreciated over a 10-year period, assuming no salvage value, and interest (10%) was charged on the average value of the investment.

Energy costs of corn processing are primarily composed of electricity, natural gas and diesel fuel usage (Table 2). Electrical usage was assumed to be

Figure 1. Economic return of steam-flaked corn above dry-rolled corn (DRC) for a 5,000 head feedyard.

similar among processing methods (17.9 kwh/ton) and priced at \$.05/kwh. Natural gas usage for steam flaking was assumed to be 1.1 mcf/ton of corn processed and priced at \$4.50/mcf which reflects current costs in Nebraska. Diesel fuel usage of .05 gal/ton of corn processed was assumed for high-moisture corn for packing in a bunker silo and use of a front-end loader while feeding. Diesel fuel was priced at \$1.31/gal, which was the 12-month average price in Nebraska for 1999. Total estimated processing costs for DRC, HMC, and SFC in 5,000 and 20,000 head feedyards are shown in Table 2.

High-moisture corn and SFC were analyzed by their return above DRC, because DRC was the simplest form of processing in performance data. Return of either HMC or SFC above DRC was calculated by the equation: Return of processing above DRC (\$/ton) = [(corn price, \$/ton) + (cost of dry rolling, \$/ton)) x (% improvement in feed/gain)] - [(corn price, \$/ton) + (cost of respective processing, \$/ton)].

Results

Results from the finishing trial are shown in Table 3. Corn processing method x urea level interactions were detected for DM intake ($P < .05$) and ADG ($P < .05$), but not for feed/gain ($P > .10$). Because feed/gain is the measurement of interest for this evaluation, only main effects of corn processing are shown in Table 4. Steers fed SFC consumed approximately 7.3% less DM ($P < .01$) than steers fed DRC and HMC diets. Daily gains were similar ($P > .50$) for all diets. As a result, steers consuming the SFC diet were 8% more efficient ($P < .001$) than steers consuming DRC or HMC diets.

Results from the performance trial are in close agreement with those reported in literature. A recent review of grain processing summarized performance from 353 research trials in which DRC, HMC, and/or SFC were fed. In this report, feed/gain was similar for steers consuming DRC and HMC, whereas steers consuming SFC were about 11% more efficient (1997 Journal

of Animal Science, 55:868-879).

Based on results from the finishing trial and calculations described above, HMC has 100% the value of DRC, whereas SFC has 108% the value of DRC. Therefore, if DRC costs \$2.00/bu, then HMC also is worth \$2.00/bu, whereas SFC is worth \$2.16/bu. It is important to note that these values are all on an equal DM basis. In addition, these values do not account for factors such as: buying high-moisture corn at a discount compared to dry corn, differences in shrink among the processing types and differences in interest on purchased corn.

High-moisture corn has 100% the value of DRC (equal DM basis). Given cost assumptions described above, HMC would result in a \$.74/ton loss in a 5,000 hd feedyard compared to DRC. Whereas in a 20,000 hd feedyard, HMC would result in \$.54/ton loss compared to DRC. These values are all on an equal DM basis and assume the same commodity corn price. Therefore, purchase of HMC would need to be discounted by these amounts, plus costs of any additional shrink and interest which may occur, in order to break even with DRC. There are several ways in which feedyards discount purchase price of HMC. One way might be a \$.02/bu discount per point of moisture above 15%. Therefore, if a feedyard purchases corn at 28% moisture, commodity price would be discounted by \$.26/bu. At the 10-year average Nebraska commodity corn price (\$2.48/bu), HMC would be purchased at \$2.22/bu (15% moisture basis). This would result in \$8.55/ton return for HMC above DRC in a 5,000-head feedyard. Again, this value does not account for any additional shrink or interest which may occur with HMC.

Steam-flaked corn has 108% the value of DRC (equal DM basis). Figure 1 shows economic return above dry rolling for SFC in a 5,000-head feedyard at various price levels for commodity corn. Regression equation ($y = mx - b$) is given so that actual return above dry rolling can be calculated at any corn price, where: y = return above dry rolling (\$/ton), m = slope of line, x = commodity corn price (\$/ton), b = intercept). The regression line for a 20,000-head feedyard ($y = .08x$

(Continued on next page)

- 5.2293) was not displayed because it was not visually distinguishable from the 5,000-head feedyard line. Corn price at which SFC breaks even with DRC can be determined by setting y equal to zero and solving for x . For a 5,000-head feedyard, corn price would need to be at least \$67.91/ton (\$1.90/bu) in order for SFC to break even with DRC. For a 20,000-head feedyard, corn price would need to be at least \$65.37/ton (\$1.83/bu) for SFC to break even with DRC. At 10-year average commodity corn price for Nebraska (\$2.48/bu; \$88.57/ton), SFC would return \$30,167 per year above DRC (\$1.65/ton on 18,250 ton/year) in a 5,000-head feedyard. In a 20,000-head feedyard, SFC would return \$135,510 per year above DRC (\$1.86/ton on 73,000 ton/year). These calculations assume 100% capacity, 20 lb/day corn intake (15% moisture basis) and do not account for differences in shrink, moisture appreciation, or labor between DRC and SFC.

Economics of HMC are greatly dependent on the magnitude of discount at which it is purchased compared to dry corn. Clearly, the largest cost associated with HMC is the initial investment in a concrete bunker. High-moisture corn can be economically attractive to a feedyard if the discount at which it is purchased is greater than additional processing costs, shrink and interest above DRC. This probably varies somewhat from feedyard to feedyard. Economics of SFC appear to be more clearly defined given assumptions made in this report. Economics of SFC are highly dependent on commodity corn price, but appear to breakeven at a corn price well below the 10-year average, even in a relatively small 5,000-head feedyard.

Effect of Corn Processing on Degradable Intake Protein Requirement of Finishing Cattle

Rob Cooper
Todd Milton
Terry Klopfenstein
Doug Jordon¹

Degradable intake protein requirement of finishing cattle is affected by method of corn processing and presumably rate and extent of ruminal starch fermentation.

Summary

Three finishing trials were conducted to determine effect of corn processing on degradable intake protein requirement of feedlot cattle. Finishing diets consisted of 82% processed corn which was either dry rolled, high moisture, or steam flaked. Degradable intake protein levels were achieved by adding 0 to 2.0% urea (DM basis) to the control diets. Estimates of degradable intake protein requirement for a dry-rolled corn-based diet were approximately 6.3% of dietary DM. Degradable intake protein requirement for high-moisture corn-based diets was approximately 10% of dietary DM. Degradable intake protein requirement for steam-flaked corn-based diet was between 7 and 9.5% of dietary DM.

Introduction

Degradable intake protein (DIP) is the fraction of feed crude protein which is available to the microbial population. In typical diets for finishing cattle, DIP is composed of both degradable true protein and non-protein nitrogen. A deficiency in DIP would have two effects. First, DIP deficiency would lower microbial crude protein

production, possibly resulting in metabolizable protein (MP) deficiency if sufficient UIP was not supplemented. Second, DIP deficiency would reduce energy yield from carbohydrate fermentation, thereby lowering volatile fatty acid production and energetic efficiency of the diet. Therefore, a deficiency in DIP may lead to reduced finishing performance even when the animal's metabolizable protein requirement has been met.

Level 1 of the 1996 NRC model predicts that DIP requirement for a typical dry-rolled corn-based finishing diet is approximately 6.8% of dietary DM. Few data exist that directly evaluate the effect of corn processing on DIP requirement. Average ruminal starch digestibilities of 78, 89 and 83% for dry-rolled, high-moisture and steam-flaked corn have been reported. It is our hypothesis that grain processing methods which increase rate and extent of starch fermentation may increase the dietary DIP requirement relative to dry-rolled corn. Objectives of these experiments were to determine DIP requirements of finishing cattle fed dry-rolled, high-moisture and steam-flaked corn-based finishing diets.

Procedure

Trial 1

Two hundred and fifty-two crossbred yearling steers (834 lb) were used in a randomized complete block design to determine DIP requirement of finishing steers fed a high-moisture corn-based diet. Steers were split into three initial weight blocks and randomly assigned to one of 12 pens and to one of four dietary treatments (21 steers per pen, 3 pens per treatment). Dietary treatments consisted of four levels of dietary DIP that were accomplished by adding 0, .4, .8, or 1.2% urea to the base diet (DM basis).
