Table 5. Effect of level of intake variation during finishing period.

Item	Level of intake variation ^a		
	No variation	Low variation	High variation
DM intake, lb/day	28.16	27.85	27.92
Rate of intake, % of daily intake/min ^b	.52	.62	.59
Ruminal pH	5.52 ^c	5.69 ^d	5.76 ^d
Area below 5.6 ^c	234.03 ^c	142.72 ^d	94.67 ^d
pHDIFF ^f	1.03 ^c	1.07 ^{cd}	1.15 ^d
pHVAR ^g	.050 ^c	.055 ^c	.072 ^d

^aNo Variation = Ad libitum. Low Variation = 2 lb/day intake variation. High Variation = 4 lb/day intake variation (DM basis).

^bSignificant interaction detected ($P = .08$). Overall means presented but not statistically analyzed.

^{c,d}Means differ ($P < .10$).

^eArea = ruminal pH units below 5.6 by minute.

^fMagnitude of daily ruminal pH change.

^gVariance of daily ruminal pH.

*Control vs Rumensin ($P < .05$).

NV = Ad libitum, no controlled intake variation.

LV = Low intake variation.

HV = High intake variation.

Figure 4. Variance of daily ruminal pH during finishing period.

(Table 5). Area of ruminal pH below 5.6 was significantly greater ($P = .07$) for the steers on control than on Rumensin, indicating more subacute acidosis with the controls (Figure 3). Area of ruminal pH below 5.6 linearly decreased ($P < .05$) with increasing level of intake variation (Table 5). The reason average ruminal pH increased and area below 5.6 decreased with increasing level of intake variation is unclear.

Daily magnitude of ruminal pH change (pHDIFF) and pHVAR were relatively constant and not affected by dietary treatment across NV and LV. However, with high intake variation, both pHDIFF and pHVAR significantly increased ($P < .05$) for the control, while remaining constant for the Rumensin treatment (Figure 4).

Therefore, results of the finishing period indicate that the use of Rumensin elevates average ruminal pH and decreases area of ruminal pH below 5.6, while stabilizing rate of intake and daily ruminal pH fluctuation at high levels of feed intake variation.

Evaluating Breakeven for Various Management Systems for Different Breed Types from Weaning to Slaughter

Cynthia Hayden

Ivan Rush

Burt Weichenthal

Brad Van Pelt¹

Summary

Two hundred twenty-four medium framed, weaned British-breed steer calves (509 lb) and 139 weaned continental-breed steer calves (542 lb) were used in two consecutive years (1994, 1995; 2 finishing pens/treatment/yr) to evaluate the effects of winter gain and length of summer grazing season on subsequent finishing performance and overall system breakeven within two

different breed types.

Calves were wintered at two rates of gain: <.75 lb/day (Slow) and approximately 2 lb/day (Fast). Calves from each wintering treatment group grazed either native range or crested wheat grass. The grazing period was from May to July (61 days; Short) or September (120 days; Long). All steers were finished on a 90% concentrate finishing diet for 131 d (Short) and 118 d (Long). Winter gain and breed type

Maximizing summer pasture gain after utilizing cornstalk grazing resulted in lower overall cost of production.

affected overall systems breakeven differently.

Introduction

As cattle frame size has increased through crossbreeding and through selection within breeds, an increasing percentage of large framed calves is now available at weaning. Producers have the option of buying medium or large framed calves, and are interested in differences in performance and cost of production when managed in various growing and finishing systems. Because of the many ways to feed and manage cattle from weaning to slaughter, economics of production systems will help producers develop management and marketing strategies for beef feeding systems.

Total efficiency (energy utilization) for a growing and a finishing period depends on the length of time of low energy feeding, level of energy restriction, level of nutrition during the compensatory period, and composition of the animal when compensatory growth is ended. Because cattle have compensatory gain potential, it allows the use of low quality economical feeds in at least part of the growing process.

The objectives of this research were to 1) evaluate the effect of winter management and length of summer grazing on subsequent finishing performance with medium framed and large framed steers, and 2) evaluate breakeven costs of production for various systems of production.

Experimental Procedures

Animals

During year one, 66 large-framed Continental cross steers (initial weight 522 lb) were compared with 128 medium-framed British cross steers (initial weight 503 lb). During year two, 73 large framed Continental cross steers (initial weight 562 lb) and 96 medium framed British cross steers (initial weight 516 lb) were subjected to the various systems. The steers were managed in a $2 \times 2 \times 2$ factorial arrangement. Factors included: breed type (British cross or

Continental cross), winter rate of gain (Slow at <.75 lb/day, or Fast at 2 lb/day), and summer grazing season (Short 58 days, year one and 63 days, year two; Long 121 days, year one and 119 days, year two). All steers were finished on a common high concentrate ration.

Initial weight and summer grazing weights (initial and final) were an average of two consecutive days' weights. Final finishing weight was a full weight that was shrunk 4 percent. All steers were implanted with Synovex S® at the beginning of the summer grazing season and were reimplanted at the beginning of the finishing phase. During the wintering and finishing phases in the feedlot, cattle were fed in two pens per treatment in both years. During the winter on cornstalks and during the summer grazing phase, all cattle were grazed together.

Winter Period

The wintering period averaged 145 days with the Slow treatment grazing cornstalks (supplemented with alfalfa hay) approximately 82 days followed by limit feeding the following diet. The winter diets for both years and for both the Slow and Fast treatments consisted of 34% dry rolled corn, 32% corn silage, 32% haylage, and 2% supplement (DM basis) and was formulated (DM basis) to contain 12.5% CP, .7% calcium, .3% phosphorus, 25 g/ton Rumensin, and 10 g/ton Tylan.

Summer Period

Wintering groups were randomly assigned by pen to either a Short or Long grazing season (2 pens per treatment). One pen (replicate) was randomly assigned to graze predominately crested wheat grass (*Agropyron cristatum* Gaertn.) pastures at the High Plains Agriculture Laboratory (HPAL) in Sidney, NE. The other pen was assigned to graze at the University of Nebraska, Panhandle Experiment Range (UNPER) in Sioux County, NE which was primarily native grass consisting of blue grama (*Bouteloua gracilis* (H.B.K.) Lag. Ex Steud.), threadleaf sedge (*Carex filifolia* Nutt.), needleandthread (*Stipa*

comata Trin. and Rupr.), and prairie sandreed (*Calamovilfa longifolia* (Hook.) Scribn.). Half of each wintering group was either grazed Short or Long season at each summer pasture location. The grazing period was from mid-May to mid-July for the early removal treatment or from mid-May to mid-September for the late removal treatment. The starting date for cattle being turned out to grass depended on the amount of forage left from the previous year of grazing, the precipitation for the current year and amount of forage growth in the current year.

Stocking rate averaged for the two locations was .31 and .28 AUM/acre for both years one and two, respectively. A mineral supplement was provided free choice for the steers grazing pasture.

Rumen fill differences after both the short and late grazing seasons were minimized by feeding a common diet of 50% corn silage and 50% haylage (DM basis) at 1.5% BW for 5 days before weighing. Weights were taken for two consecutive days before feeding in the morning.

Finishing Period

Steers were fed a common finishing diet for 137 days (Short) and 118 days (Long) for year one and 125 days (Short) and 118 days (Long) for year two until it was estimated that 70 percent of the steers had reached the Choice grade. The finishing diet for both years was a high concentrate corn diet which contained 10% DM from corn silage. The rations were formulated to contain (DM basis) 12.5% CP, .6% calcium, .3% phosphorus, 25 g/ton Rumensin, and 10 g/ton Tylan. Three step up diets were utilized which contained 50%, 28%, and 13% roughage (DM basis) with each step up ration fed for approximately 5-7 days. Carcass data were collected for both years after a 24 hour chill (Table 2).

Economics

Economic analysis for each system included standardized costs for both years for all inputs. Breakeven prices

(Continued on next page)

were used to evaluate the comparative economic costs of each system. The charges used for both years were: feedlot yardage, \$.25/day; purchase price, \$95/cwt; interest rate, 9%; feed cost for the Fast winter group, \$.45/day; feed cost for the Slow group, cornstalks for 3 months at \$.15/day and limit fed for 2 months, \$.45/day; summer grass, \$.33/day; and feed cost for finishing, \$.05/lb.

Statistical Analysis

Data within in each trial were analyzed by analysis of variance using the General Linear Models procedure (SAS, 1985). The data for the economic analysis were evaluated for differences in mean values by use of Duncan's multiple range test for years one and two. Experimental design was a completely randomized design with a $2 \times 2 \times 2$ factorial treatment arrangement, with finishing pen as the experimental unit. It was not possible to pool the two years because of a treatment x year interaction ($P < .10$).

Results

Cattle wintered at a Slow rate of gain compensated during the summer grazing period, as would be expected, and gained more than those wintered at a

faster rate ($P < .01$; Table 1). The Continental cross cattle gained more on pasture regardless of previous winter gain the first year ($P < .10$), however summer gains were similar in both breed types the second year. The winter gain was slightly higher the second year for both the British cross and the Continental cross, and perhaps the Continental cross were near the same body condition as the British in year two when going to grass. Also the summer gain in year two tended to be higher than in year one for both breed groups. The differences in physiological maturity of the Continental and British cross cattle may not have been as great as in the previous year.

When nutrients are not restricted, perhaps the larger-framed cattle can continue to take advantage of their growth potential. Even though grass consumption was not measured, it is probable that the larger compensating cattle consumed considerably more forage.

During the finishing phase there was not a consistent carryover effect of winter gain in both years. Finishing dry matter intake for both years shows the Continental cattle consumed more than the British cattle regardless of winter or grazing treatments. In year two, cattle that were wintered at a Slow rate gained

faster and were more efficient than those that were wintered at a faster rate. Because there was a lack of compensatory growth difference exhibited between the two breed types during the summer grazing period, perhaps these differences were exhibited during the finishing phase. Finishing ADG was higher for steers that finished after the Long grazing season compared with those grazed for the Short season for both breed types during year one. For both years, hot carcass weights and rib-eye areas were higher for Continental cattle, regardless of winter gain or grazing season.

Finishing feed to gain ratios (Table 2, year one) were higher ($P < .10$) for the Short grazing season than the Long for both breed types. For year one, the combination of both winter gains with Long season grazing resulted in the lowest finishing feed to gain ratio for both British and Continental cattle.

The most desirable breakeven for year one was for Continental cattle wintered Fast and summer grazed the Short season, and for year two it was for British cattle grazing cornstalks for the winter and summer grazed for the Short period (Figure 1). The letters used to identify boxes in Figure 1 are in the order of breed type, winter gain, and grazing season defined in Tables 1 and

**Figure 1. Breakeven analysis of management systems, coded from top three lines, Table 2.**

2. In year two, Continental cross cattle that grazed cornstalks in the winter and grazed in the summer for the Long season had the highest breakeven. The difference in the two years may be explained by the biological differences in the cattle and the summer forage available.

Total costs for year two were lower for the Short summer grazing group than the Long season group. Total costs for year one were lower for the British cross cattle compared to the Continental cattle when both grazed cornstalks during wintering. Breakeven analysis was considerably different between years. Year one had a Continental group with the lowest breakeven which was the highest the following year. Since the two years of results were so different in the analysis, it shows that more research is needed to find out which management system may be the best in particular years.

¹Cynthia Hayden, former graduate student; Ivan Rush and Burt Weichenthal, Professors, Animal Science, Brad Van Pelt, research technician, Panhandle Research and Extension Center, Scottsbluff.
