Table 2. IVOMD^a and CP^a content of irrigated and dryland bean components.

	Crude Protein, %DM		IVOMD ^a	
	IR ^a	DL ^a	IR ^a	DL ^a
Pods	7.13	5.73	64.8	63.5
Stems	6.03	5.67	38.7	41.5
Leaves	12.75	11.94	38.7	39.6

^aIVOMD = in vitro organic matter disappearance; CP = crude protein; IR = irrigated; DL = dryland.

tions throughout the trial showed that initially, calves spent considerable time in bean fields eating residual beans off of stems. As time progressed, cattle began to spend more time in corn fields. Even though calves were allowed an adaptation period before the beginning of the trial to acclimate themselves to grazing cornstalks, it is likely that the beans were more readily available initially, therefore calves removed the soybeans first. Residual corn values (Table 1) showed calves grazing only corn had slightly more corn per head compared to cattle on the soy/corn; however, due to sampling variation there was no statistical difference. Corn fields in both treatments should have been relatively equal in terms of downed corn. Cornfields for both treatments were actually one large field divided by an electric fence. Residual bean values showed that calves on the soy/corn treatment had access to soybeans to make the overall residual grain values closer; however, the soybeans did not entirely make up the difference.

Table 2 shows the characterization of soybean material from irrigated and dryland fields. Components from the irrigated fields were consistently higher in CP than dryland components. Higher CP values typically correspond to higher intakes depending on diet; however, because calves also had access to corn residue, it is doubtful there were any intake differences between bean fields. Excluding pods, IVOMD for dryland soybean plant components were greater

than those of the irrigated. Irrigated stems and leaves may have been less digestible because of irrigation, thereby lowering IVOMD values. Legumes are known to deposit more structural carbohydrates during periods of adequate water in contrast to periods of moisture stress. The summer preceding the trial was relatively dry, causing a water deficit in the dryland beans compared to irrigated beans. *In vitro* organic matter disappearance for the leaves was lower than values for other components. This finding was surprising; however, it may have been due to weathering that occurred after the leaves had dropped from the plant.

The assumption made about the bean fields was that calves would only consume pod material. Even though pod CP values were low, IVOMD values for both dryland and irrigated beans support the idea that cattle would benefit from this highly digestible material.

Comparison of IVOMD values for both corn plant components and soybean plant components show them to be similar. Corn husks are much like pods with an IVOMD of roughly 70 percent. Corn leaves compare to bean stems and leaves with an IVOMD of approximately 42 percent. While values are similar, the corn residue would supply more lb of available DM per acre.

Gary Lesoing¹

Cattle perform similarly on either tillage practice; however, yearly circumstances may affect overall performance. Calves grazing winter stalks will not adversely affect corn yields.

Summary

A grazing trial was conducted in the fall and winter of 1995-1996 to compare how conventional and ridge-till systems would affect animal performance. Calves on each treatment performed similarly showing no differences in gains. These results closely follow three previous years of data that show cattle can be expected to gain equally on each tillage practice. A year x treatment interaction ($P < .05$) was detected when data from all four years

(Continued on next page)

were pooled, indicating that gains may be slightly affected in each practice, depending on specific yearly circumstances such as precipitation or weed infestations. Yield data over the past four years has shown that grazing stalks will not adversely affect corn yields on either tillage practice.

Introduction

Cornstalks provide a low cost and efficient source of winter feed for cows and calves to reduce wintering costs. Calf gains are often low resulting in a compensatory gain period in the spring when cattle are placed on pasture or put into the feedlot. To truly evaluate costs and benefits of grazing cornstalks, cattle gains on different tillage methods, as well as subsequent effects on crop yields, must be evaluated. Since the fall of 1992, studies at the University of Nebraska have been conducted to determine cattle performance and subsequent crop yields in ridge-till and conventional disk plant irrigated corn production systems. In the ridge-till production system, residual corn material settles into the furrows. Under snowy and/or muddy conditions, available forage may be covered or trampled, as cattle tend to walk in the furrows.

Objectives of this trial were to continue to build on previous work comparing cattle performance and grain yields on conventional and ridge-till fields.

Procedure

Experiments were conducted during the fall and winters of 1992-1993, 1993-1994, 1994-1995, and 1995-1996 to evaluate performance of calves grazing cornstalks on conventional and ridge-till fields. A 100-acre irrigated corn field under a linear move irrigation system was divided into six fields allowing three fields for each tillage practice. One-hundred-nineteen, 117, 117, and 104 weaned crossbred steers were assigned randomly to one of six fields in 1992-1993, 1993-1994, 1994-1995, and 1995-1996, respectively. Cattle were weighed on two consecutive days at the beginning and end of each trial

after being limit fed for a period of three days to standardize differences in gut fill. Corn fields were stocked at 1.2 animals per acre according to previous irrigated corn residue work done at the University of Nebraska. Stocking rates were based on lbs of available husk and leaf DM material per acre.

Before cattle placement on stalks, each field was sampled in four random 250 x 2.5 ft strips to determine amount of residual corn. Full and partial ears were collected and shelled to determine bushels per acre of residual corn in each field. No residual corn estimates were collected before the 1992-1993 trial. Calves in all fields were supplemented with a 36% CP supplement at 1.5 lb/hd/day (as-is). To determine impact of grazing, yields were measured by machine harvest the following fall from grazed and ungrazed areas of each tillage method. Ungrazed areas were maintained each year. Calves were placed on stalks approximately December 1 and removed approximately February 1 in each year.

Results

Cattle performance for the 1995-1996 trial are shown in Table 1. Calves on conventional fields outperformed cattle on ridge-till fields; however, there were no statistical differences in gains. Precipitation events during the trial were minor, with only two measurable snowfalls occurring, each totaling 3.5 in. Snow in each instance was gone within two to three days. Temperatures during the trial were slightly below normal for the period when compared against the local 30-year average (22.7°F). The lower temperatures tended to keep the ground frozen and available forage from being trampled in mud between ridges.

Residual corn estimates for the trial are also shown in Table 1. There was no difference between conventional and ridge-till fields for the 1995-1996 trial; however, high sampling variation existed. More samples should have been collected in each field to make the estimates more reliable.

Table 2 shows cattle gains over four years of grazing. Only during the 1993-1994 trial was a difference seen in gains

between conventional and ridge-till fields ($P < .10$). Gains in 1995-1996 were greater than in previous years; however, there were no treatment differences. Added gains in 1995-1996 were likely a result of the dry summer which preceded the trial. Previous trials at the University of Nebraska have shown that cattle gains tend to be greater on stalks following a dry summer due to an increase in residue quality. Increased quality combined with a cold and dry grazing period allowed for excellent calf gains. Performance data over all four years were pooled to find overall averages comparing conventional and ridge-till fields. Averages showed similar gains. A year x treatment interaction ($P < .05$) was detected in the pooled data set. This can be explained by environmental differences which occurred in each year. In 1992-1993, muddy conditions resulted in calves on conventional fields having higher gains. Calves on ridge-till fields trampled available forage which had collected in the furrows where they tend to walk. In 1993-1994, a grassy weed infestation and lower plant populations in conventional fields resulted in low DM production and lower animal gains compared to ridge-till fields. Also, grazing conditions in the ridge-till fields were excellent with

frozen ground and little mud. This trial also showed a difference in residual corn estimates which partially accounted for the increased gains seen in the ridge-till fields.

Table 3 shows machine harvested yields and residual corn estimates broken down by year. No residual corn samples were collected before the 1992-1993 trial. Yields were measured in the

fall following grazing in the previous year. Yields for both grazed and ungrazed areas were variable from year to year showing no definitive trends. Residual corn estimates were different ($P < .05$) only in 1993, the same year in which a difference was found in cattle gains indicating that gains are somewhat dependent on residual corn. In 1994 and 1995, residual corn estimates were much closer as were cattle gains.

Continuous vs Rotational Stocking of Warm-Season Grasses at Three Stocking Rates

Bruce Anderson
Mike Trammell
Terry Klopfenstein¹

caused big bluestem to replace little bluestem and indiagrass and caused a slight decrease in stands.

Continuous stocking changes species composition of grass stands and may affect long-term productivity. Rotational stocking lengthens the grazing season but may not increase total gains.

Summary

Pastures containing big and little bluestem, indiagrass, sideoats grama, and switchgrass were stocked with 2.1, 2.7, and 3.3 yearling steers/acre from June to August. Continuous stocking and six-paddock rotations were used. Grazing terminated early on most continuously stocked pastures due to low herbage mass. As stocking rate increased, ADG declined; continuous stocking produced highest (1.6 lbs) and lowest (.69 lbs) ADG. Gain/acre was unaffected by stocking rate using rotational stocking (224 lbs/acre) but declined from 250 to 133 lbs/acre as stocking rate increased using continuous stocking. Continuous stocking

Introduction

Many studies have shown that grazing systems including warm-season grass pastures are more productive than grazing only cool-season grasses. In addition, numerous reports extol the benefits of rotational stocking, but research comparisons rarely have found large differences in animal gains between continuous and rotational stocking. Stocking rate is the most important controllable factor influencing animal and pasture performance, regardless of the grass grazed. Despite their importance, few studies have evaluated either stocking rate or grazing methods of warm-season grasses.

Stocking rate and grazing methods influence animal and pasture performance several ways. Gain per animal remains constant at stocking rates below a critical level and decrease above that level. Gain per acre increases with stocking rate until gain per animal becomes so low that gain per acre declines rapidly with further increases in stocking rate. Plant species differ in their

response to grazing so botanical composition may change under various stocking rates and combinations of grazing and rest.

This study examined botanical changes in mixed stands of warm-season grasses and measured yearling cattle gains as influenced by continuous or rotational stocking at three stocking rates.

Procedure

Eighteen seeded pastures containing a mixture of big bluestem (*Andropogon gerardii*), indiagrass (*Sorghastrum nutans*), sideoats grama (*Bouteloua curtipendula*), little bluestem (*Schizachyrium scoparium*), and switchgrass (*Panicum virgatum*) were grazed at the Agricultural Research and Development Center near Ithaca, NE during 1993-1995.

Pastures contained about 3.3 acres and were grazed as a 3 x 3 factorial with 2.1, 2.7, and 3.3 yearling steers per acre. Continuous stocking and six-paddock rotations with either fixed (5-day graze, 25-day rest) or variable graze/rest periods were the grazing methods. Variable graze/rest periods were
